#### Abstract

In this dissertation, we build a simulator allowing to reproduce the major features of the French system of taxes and benefits. Devices included in the simulator are Income Tax, CSG, CRDS, PPE, RSA, Family Allocations, Family Complement. We provide a detailed presentation of all these devices that are central to the French system, in order to make them available to non-French speakers.

Then, we run our simulator on INSEE ERFS 2006 data in order to derive the major economic features of the existing system in terms of redistribution and marginal explicit and implicit tax rates. This analysis is conducted both at the household level (which is the one at which these devices actually operate) and at the individual level (which requires making assumptions as regards the intra-bousehold bargaining process for the allocation of taxes and benefits). At the household level, the resulting average contribution curve is of a complex form, with kinks. The resulting marginal rate curve is, as expected, $U$-shaped. At the individual level, we also find $U$-shaped marginal tax rate curves, but more erratic due to the practice of family income splitting and its effect on second earners, and with higher marginal tax rates for women than for men at the bottom of income distribution.

Finally, we simulate various fundamental reforms of the system, that involve putting together all devices named above into a unified average tax rate scheme (as opposed to current marginal tax rate schemes), and an individual treatment of taxpayers (as opposed to the existing family income splitting system). Supposing different intensive and extensive labor supply elasticities for men and for women, we then estimate labor supply responses to these fundamental reforms, and their potential efficiency gains.

We find that fully individual tax schedules have strong perverse consequences in terms of budget balance and in terms of efficiency, mostly by increasing marginal rates at the bottom of the income distribution. Then, semi-individual schedules seem to allow for potentially significant efficiency gains, but rather concentrated at the upper middle and top of the income distribution. With a 0,5 intensive and a 0,98 extensive labor supply elasticity for women (and no elasticity for men), we find an increase in labor supply of $1,4 \%$. However, the question of the transition between a household-based system at the bottom of income distribution and an individual one at the top, as well as the question of how the presence of children should be taken into account, remain problematic. A more neutral treament of children could raise labor supply gains up to $3 \%$.

## Remerciements

Je tiens en premier lieu à remercier Thomas Piketty pour toute son aide, sa patience et sa très grande disponibilité.
Un grand merci à Camille Landais pour une précieuse aide méthodologique.
Merci aussi à Magda Tomasini et Hélène Chaput de m'avoir permis d'accéder aux données ERFS 2006, et de m'avoir accueilli à l'INSEE.

Merci à mes parents et à ma soeur pour leur infaillible soutien.
Enfin, je suis très reconnaissant à l'École normale supérieure pour les excellentes conditions de travail qu'elle m'a offertes depuis 2006.
$\grave{A}$ Alfred Bittendiebel, mon grand-père.

> (...) U.S. income tax laws have placed a large burden on the earnings of married women.
> When a married couple chooses to enjoy the tax advantages of filing jointly, the first dollar earned by the wife is in effect taxed at the same marginal rate as the last dollar earned by the busband. Harvey S. Rosen, 1977

## 1 Introduction

Women's labor supply elasticities are known to be higher than those of men. It is now considered conventional wisdom that according to Ramsey's "inverse elasticity" principle, this finding implies that women should face lower marginal tax rates than men.

However, the French joint taxation system seems to do exactly the contrary: women often being second earners, they often face, in reality, higher marginal rates of taxation than men.

There are two main factors that may help understand the persistence and the relative popularity of the joint filing system in French:

First, its design leads to potentially strong tax reductions to married couples, and practically eliminates any kind of "marriage penalty".

Second, it seems that there is a great concern about "horizontal equality", meaning that people with the same standards of living should not face different tax rates. The French system, organized around the concept of Family Income Splitting (Quotient Familial) is mostly aimed at that: roughly speaking, households that have the same number of mouths to feed are to be taxed equally, regardless of the distribution of income within the household.

However, without necessarily denying the importance of this kind of horizontal equality, it might be interesting to try and know at what cost it comes, mostly in terms of the efficiency losses induced by its strong distortion on the labor supply of women.

As regards taxes and transfers, the French system seems like a very complex one. It seems to be the outcome of a long series of reforms aimed at solving particular issues, rather than
the result of an unified design. As of today, it consists of a number of little devices, run by different government organs, and, according to its opponents, it has grown more and more difficult to understand for workers and taxpayers themselves.

Here are a few illustrations of the current system's complexity: some devices are aimed at the individual while others work at the household level - the concept of household being itself being subject to variations across devices -, and their eligibility criteria are not the same. Furthermore, these devices have different ways of taking into account the presence of children or spouses inside households, and the concept of income they use in order to determine tax payments or transfer entitlements is also not the same. On top of that, payment schedules are very different across devices -some taxes and benefits being paid from quarter to quarter, others with a one year delay-. All these elements make it practically impossible for a citizen to accurately forecast her actual available income at the end of the year. This complexity alone probably interferes with one's optimal labor supply decision.

Hence, the first goal of this paper is to provide a simulator, currently written in SAS language, that integrates the most significant of these devices. It aims at providing a general vision of the French system in terms of average rates of contribution (positive or negative), and marginal retention rates. This in turns sheds light on the redistribution features and effects on labor supply incentives of the existing system.

This allows to provide the non French-speaking with a presentation of the various mechanisms and features of the so-called "French system".

Then, in order to estimate the efficiency losses caused by the existing practice of family income splitting that tends to increase marginal tax rates faced by household's second earners, we simulate various reform scenarios. Our goal is to explore reform possibilities that would allow substantial efficiency gains (through the reduction of distortions induced by joint taxation), without leading to unnecessary redistributive effects, and keeping tax revenues and transfer spendings at reasonable levels.

These scenarios all have in common a simplification of the system: all studied devices (Income Tax, PPE, CSG, CRDS, RSA, Family Allocations, Family Complement) are compounded and merged into a simple, legible tax schedule - where taxes can be positive or
negative - that expresses the average tax rate as a function of gross labor income. This simplification has three main virtues: First, it replaces the numerous existing devices by one single device; second, it replaces the existing schedules that are expressed in marginal tax rates by a schedule expressed in terms of average tax rate, which makes it more legible and understandable; third, it simplifies the concept of income, by expressing tax rates as a function of gross labor income only, as opposed to today's devices, that each use a different measure of income (among gross, taxable and net income).

However, our scenarios differ by the way they deal with the issue of individualization: indeed, it is very likely that implementing some degree of individual filing will lead to efficiency gains, but it is not obvious that such a practice can be beneficial for all levels of income (especially at the bottom of income distribution).

Our scenarios do not fully deal with the issue of the optimal tax and benefit treatment of children, since this question goes beyond the scope of this study. Children-related features of the existing system are described and assessed, but the way they should be reformed does not yet seem obvious. For now, we replace all children-related gains of the existing system by a lump-sum transfer of $1780 €$ per child and per year (which is the average amount of children-related gains per child in the existing system), to be divided between spouses.

We first experiment a scenario that consists in a full individualization of the system, in which the computation of payment or benefits is entirely made at the individual level, and does not take household composition into account at all. Tax and benefit schedules are designed to be as close as possible to the ones already faced by single individuals in the current system (without any effect of having children or being married).

Our second scenario is close to the first one, except that the reference situation is the tax and benefit schedules currently faced by couples (as opposed to single individuals).

Given the difficulties raised by the two first scenarios, we propose a third system, based on partial individualization: higher income taxpayers would face an individual system, while lower income taxpayers would still face a household-based system. This system has the most interesting efficiency features, but raises difficulties as regards the transition between the household-based system at the bottom of income distribution and the individual-based system at the top.

For these three scenarios, we evaluate possible efficiency gains drawn from responses to changes in marginal tax rates, and give an order of magnitude for the GDP growth it could trigger.

It should be stressed that this second contribution (scenario simulation) is for exploration purposes only, and that a number of other scenarios could be investigated. Certainly, some model refining, as well as a more normative investigation of the various policy tradeoffs that we face is still required.

## 2 Related Literature

The fundamental contribution that underlies most of the arguments and questions around individualization of tax and benefits systems is Ramsey's (1927) "inverse elasticity rule", according to which, in order to reduce distortions, goods that a are supplied inelastically should be taxed at a higher rate than goods whose supply is more sensitive to variation in prices (and hence taxation).

Various empirical studies have shown that women tend to have a more elastic labor supply than men, among which the study of Rosen (1977), quoted in the introduction. Boskin and Sheshinski (1938) have made the argument stronger, concluding that the optimal tax rate that men should face "would be roughly twice that on wives".

This debate became more present in the recent years, that lead to more polemic publications, like "Taxing Women: how the marriage penalty affects your taxes", by McAffery in 1999.

It seems that the general idea that emerges of literature is that women and men should not be taxed on a joint filing basis, and that individual or selective taxation would be better. Individual taxation means that women and men are taxed separately, but face the same tax schedule; selective taxation means that women and men not only are taxed separately, but also face different tax schedules.

Kleven, Kreiner and Saez (2007) show, in a very broad framework, that the optimal taxation of couples should follow the principle of negative jointness, meaning that the tax rate of one person should, in order to maximize social welfare, decrease in the earnings
of the spouse. When the first earner's income becomes large, tax on the second earner's income should even tend to zero. These results are shown in models in which the second earner makes a binary choice between entering or not entering the labor market, as well as in models where both spouses make continuous labor supply decisions. Proof is brought using much less restrictive assumptions than previous literature, since no separability in the couple tax function is assumed: the income tax may be computed depending on the income of spouses in any nonlinear fashion.

However, selective taxation faces the strongest political opposition, because taxing people at different rates seems to be against equality principles. In that respect, a recent contribution by Alesina, Ichino and Karabarbounis (2008) brought the debate further, by bringing together an analysis of within-household welfare repartition induced by various forms of taxation and an investigation of the within-household bargaining mechanisms that lead to the division of family chores and to each spouse's participation in the labor market. One strong insight of this paper is that it is likely that women's higher sensitivity to taxation in terms of labor supply needs not be a matter of individual characteristics, but could instead be the result of asymmetric bargaining power within the couple. This argument can probably make selective taxation more politically acceptable:

Indeed, as Alesina et al's contribution models this intra-household bargaining and thereby endogenizes each spouse's labor supply elasticity, it shows that there exist schemes of selective taxation (called Gender Based Taxation (GBT), and advocated as a powerful policy tool) that can help decrease aggregate distortions, increase social welfare while remaining feasible from the point of view of government budget. In that case, Gender Based Taxation corrects for "social dissonance" (Apps and Rees, 1998), between preferences of society who does not value men over women, and the yet persisting asymmetry in bargaining power, which leads to unequal access to the labor market between spouses. They show that the same results apply if the difference between men and women does not result from asymmetry in bargaining power, but from a comparative advantage of the woman in the "production of the household good" (family chores).

Hence, it may be interesting to investigate this idea in France, where joint taxation is
the general rule for couples, because of the often large fiscal incentives associated to it ${ }^{1}$ However, in terms of political acceptability, it might be better to begin with an study of individual taxation, before conducting an analysis of specific taxation (GBT).

A first simulation of income tax individualization in France has been conducted by Échevin (2003). Contrary to this dissertation, is focuses on income tax only. Échevin's contribution finds, in 2002 income tax data, that about $46 \%$ of married couples benefit from an average "marriage subsidy" of $1080 €$ per year, and that $22 \%$ face a marriage penalty of $185 €$ per year. This marriage penalty is not essential to the French income tax system, and is more of a side effect of a few specific features, like the décote (described in section 4.2.3. This is why its amount is relatively low, when compared to the marriage subsidy faced by other couples.

Then, Échevin simulates income tax individualization while keeping the current tax schedule unchanged, and keeping intact the principle of Family Quotient (which essentially yields a per-child tax reduction that increases in the level of income, and that increases more than proportionally in the number of children declared). The outcome of such a setting is a substantial increase in income tax revenues, as well as efficiency gains. However, the idea of suppressing couple income splitting why leaving the income-splitting effect of children can seem unlikely to be implemented in the future.

Labor supply elasticities of women are then estimated with the help of wage equations and participation equations. The global results is that, taking into account the effect on the labor supply of women, individualization reduces vertical inequality (across deciles of income), and leaves horizontal inequality (across households with the same standard of living but with potentially different family structures) unchanged.

Our purpose it to conduct a broad analysis of the French system, including other taxes and transfers that play an important role in the determination of household's end-of-theyear available income. We include in our analysis different taxes or benefit devices like CSG, PPE, RSA, Family Allocations ${ }^{2}$. The most significant new device in terms of their

[^0]effect on marginal rates of taxation being PPE and RSA, which have been introduced after Échevin's study.

## 3 labor income distribution and the issue of second earners

### 3.1 Source data

In this study, we work with 2006 French data on incomes, taxes and social security benefits, called ERFS (Enquête revenus fiscaux et sociaux, survey about fiscal and social security incomes).

ERFS is a study that puts together different sources of information (labor market survey data, data from income tax declarations, social benefits data, data about capital incomes $\sqrt{3}$, in order to provide a broad view of labor income, taxes and benefits of French households. It is made every year by the French National Institute for Statistics and Economic Studies, INSEE, on a sample of roughly 36000 households and their corresponding 44000 income tax declarations. Every tax declaration is linked to its originating household, so it is possible to keep track of changes in situations (like marriage or divorce) that lead people to file several tax declarations in the same year.

We mostly focus on income tax declarations, and compute other tax and benefits from these figures. This allows to build a simulator that needs to be fed little data (only those of tax declarations), and can simulate most figures (taxes, social security contributions, various benefits) from the information contained in tax declaration forms. This also provides an unified simulator in order to compute average rates and marginal rates of taxation and benefits.

Income distribution in the data has been reweighted to match the distributions described in Landais (2007), who were computed on more exhaustive French income tax data. This allows better coverage of high-income households.

Table 1 shows summary data about income aggregates, and provides a comparison between our computations and official aggregates published by the French tax administration ${ }^{\text {4 }}$

[^1]|  | Computed Aggregates | Official Aggregates | Ratio |
| :--- | ---: | ---: | ---: |
| Total income | $884,53 \mathrm{Bn}$ | $886,02 \mathrm{Bn}$ | $99,83 \%$ |
| Wages | $526,72 \mathrm{Bn}$ | $527,90 \mathrm{Bn}$ | $99,77 \%$ |
| unemployment and sickness <br> benefits | $27,39 \mathrm{Bn}$ | $27,24 \mathrm{Bn}$ | $100,53 \%$ |
| Pensions and rents | $212,05 \mathrm{Bn}$ | $212,37 \mathrm{Bn}$ | $99,84 \%$ |
| Non salary-earning <br> professions | $58,90 \mathrm{Bn}$ | $59,48 \mathrm{Bn}$ | $99,02 \%$ |
| Land revenues (revenus <br> fonciers) | $20,98 \mathrm{Bn}$ | $20,50 \mathrm{Bn}$ | $102,34 \%$ |
| Asset income (revenus des <br> capitaux mobiliers) | $25,05 \mathrm{Bn}$ | $25,11 \mathrm{Bn}$ | $99,74 \%$ |
| Capital gains (Plus values à <br> $16 \%)$ | $13,40 \mathrm{Bn}$ | $13,39 \mathrm{Bn}$ | $100,10 \%$ |

Table 1: Taxable income of French tax-paying households, as present in the data
Note: it should be stressed that data contained in the three last lines is quite inaccurate. Indeed, there are many tax exemptions that apply to these kinds of income, and that make a significant portion of them invisible in income tax data. What we observe here is barely one third of actual estate incomes (estimated to roughly $151 \mathrm{Bn} €$ by the Conseil des Prélèvements Obligatoires). This is not a problem, since our work is focusing on labor income, but these tables should not be used in order to work on French estate income. The INSEE Enquête Patrimoines would be much more appropriate.

The amount of taxes and transfers on 2009 income is not yet fully known. Many parameters (among which the formula for income tax) will be set by next year's appropriation bill (loi de finance), during the fall and the winter. Therefore, in this paper, our simulation aims at reproducing the 2008 situation. Hence, we increase all revenues observed in our 2006 data by the growth of minimum wage over the two previous years, which is $5,32 \%$. Then, all taxes and benefits that we use are computed on 2008 revenues (but taking into account RSA, the device replacing the guaranteed minimum as of 2009). However, they are not all paid in 2008. For example, income tax is paid in 2009 on 2008 incomes, while most (but not all) benefits are paid immediately, on the basis of current income. Table 4.6 summarizes the timing of tax and benefit computation and payment. We come back to this issue in section 4.

### 3.2 Income composition: the prevalence of labor income

Table 2 summarizes actualized data on income. It shows the repartition of labor income between wages, illness and unemployment benefits, pensions and rents, income of non wageearning workers. The concept of income presented here is taxable income, because it is the one observed in the data. The relationship between gross income, net income and taxable income is dealt with in section 4.1. In our final simulations, we shall mostly use the concept of gross income, since the simplifications we suggest will make the use concepts of taxable income and net income useless in order to determine tax rate.

In the next subsections, we present a few facts about the distribution of incomes across households, individuals, and within households. In the case of wage-earning workers, these figures can easily be converted to gross income, as explained in section 4.1. The following tables only include working-age households and individuals, between $25^{6}$ and 65 . Broader statistics, including younger people and retirees, are available in section A. 1 of the appendix.

[^2]| (in 2008 value) | Total labour income | wages | unemployment and sickness benefits | pensions and rents | income of non wageearners |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Aggregate income | 868,9 Bn | 554,8 Bn | 28,9 Bn | 223,3 Bn | $62,0 \mathrm{Bn}$ |
| Average income per household | 24473 | 15625 | 813 | 6291 | 1745 |
| repartition | 100,0\% | 63,8\% | 3,3\% | 25,7\% | 7,1\% |
| Average for non-zero incomes * | 25808 | 24495 | 6066 | 17324 | 28773 |
| men's income (sum) women's income (sum) | $\begin{aligned} & 520,5 \mathrm{Bn} \\ & 343,6 \mathrm{Bn} \end{aligned}$ | $\begin{aligned} & 336,1 \mathrm{Bn} \\ & 216,0 \mathrm{Bn} \end{aligned}$ | $\begin{aligned} & 16,5 \mathrm{Bn} \\ & 12,3 \mathrm{Bn} \end{aligned}$ | $\begin{array}{r} 121,6 \mathrm{Bn} \\ 99,7 \mathrm{Bn} \end{array}$ | $\begin{aligned} & 46,3 \mathrm{Bn} \\ & 15,7 \mathrm{Bn} \end{aligned}$ |
| men's income (average) * | 14659 | 9467 | 464 | 3425 | 1303 |
| women's income (average) * | 9683 | 6086 | 346 | 2809 | 441 |
| Number of tax declarations | 35,50 M | $22,64 \mathrm{M}$ | 4,75 | 12,89 M | 2,23 M |
| Number of individuals with positive labour income | $43,65 \mathrm{M}$ | $27,74 \mathrm{M}$ | 4,89 M | $15,79 \mathrm{M}$ | $2,37 \mathrm{M}$ |
| number of men with positive income in each category |  |  | 2,44 M | 6,83 M | 1,62 M |
| number of women with positive income in each category | $21,64 \mathrm{M}$ | 13,20 M | 2,45 M | 8,95 M | 0,75 M |
| Overall number of individuals: | 48 M |  |  |  |  |

Table 2: General statistics about ERFS 2006 data: repartition of labor income between wages, illness and unemployment benefits, pensions and rents, income of non wage-earning workers; and number of households and people (men and women) falling into each category

* These averages are computed without taking into account observations with zero income. Hence, the aggregate values of these variables can be found by multiplying these figures by the number of non-zero observations.
Note: from now on, all incomes are actualized to 2008 value.

### 3.3 Income distribution across households

Table 3 shows the distribution of labor income across households. Here again, we mean household in a fiscal sense, ie people filing a revenue declaration together. Lower deciles of income are mostly constituted by single-earners. The "age" column is the average age of all individuals belonging to the fractile. We only take into account the income of spouses. Their dependents's income is left aside for now, and is quantitatively quite unimportant (it represents $2,7 \mathrm{Bn} €$, which is less than $0,3 \%$ of taxable labor income observed in the data).

| fractile | $P_{f}$ | gross income | taxable income | net income | average age |
| ---: | ---: | ---: | ---: | ---: | ---: |
| All |  | 33565 | 27350 | 26568 | 43,6 |
| $0-10$ | 0 | 1191 | 963 | 935 | 41,1 |
| $10-20$ | 5428 | 8763 | 7086 | 6882 | 42,2 |
| $20-30$ | 11693 | 13996 | 11318 | 10992 | 42,0 |
| $30-40$ | 16069 | 17877 | 14457 | 14040 | 41,2 |
| $40-50$ | 19474 | 21211 | 17153 | 16659 | 41,4 |
| $50-60$ | 22984 | 25105 | 20302 | 19718 | 42,4 |
| $60-70$ | 27373 | 30328 | 24526 | 23820 | 44,1 |
| $70-80$ | 33639 | 38045 | 30800 | 29914 | 44,9 |
| $80-90$ | 42999 | 50165 | 40664 | 39496 | 44,8 |

| $99-99.9$ | 111158 | 152444 | 129638 | 126089 | $14,8 \%$ | 48,1 |
| $99.9+$ | 278896 | 497847 | 445054 | 433464 | $11,7 \%$ | 48,2 |

Table 4: Distribution of labor income across individuals between 25 and 65 ( $34,34 \mathrm{M}$ individuals)

* fractile of individual gross income.
$P_{f}$ is the fractile's lower limit.
can see, about $15 \%$ of women do not have any labor-related income, which is three times as much as men. Again, it needs to be stressed that we do not observe all sources of income here (starting with social minima): this table only treats labor income.

This strong asymmetry between men and women can be attributed to countless factors. Our hypothesis here is that there is at least a portion of these numerous non-working women that would be ready to work if they faced lower marginal rates of taxation. The fact that the proportion of zero income women is highest between 50 and 65 could comfort this hypothesis, since they tend to have husbands with higher earnings, which makes them face a high marginal tax rate.

### 3.5 Income distribution within households: who are the second earners?

The issue of second earners is central to our question, since in most cases the fact of being the second earner leads to higher marginal rates of taxation. This issue is illustrated in section

|  | Men |  |  | Women |  |  | All |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| age | $\mathrm{Y}=0$ | $\mathrm{Y}>0$ | \# All | $\mathrm{Y}=0$ | $\mathrm{Y}>0$ | \# All | $\mathrm{Y}=0$ | $\mathrm{Y}>0$ | \# All |
| 18-24 | 4,54\% | 95,46\% | 1777085 | 12,38\% | 87,62\% | 1765885 | 8,45\% | 91,55\% | 3542970 |
| 25-29 | 4,79\% | 95,21\% | 2100225 | 13,85\% | 86,15\% | 2100163 | 9,32\% | 90,68\% | 4200388 |
| 30-39 | 5,61\% | 94,39\% | 4658873 | 16,52\% | 83,48\% | 4648122 | 11,06\% | 88,94\% | 9306995 |
| 40-49 | 6,21\% | 93,79\% | 4531307 | 16,78\% | 83,22\% | 4636367 | 11,56\% | 88,44\% | 9167674 |
| 50-59 | 6,32\% | 93,68\% | 4215250 | 22,04\% | 77,96\% | 4387982 | 14,34\% | 85,66\% | 8603232 |
| 60-64 | 3,03\% | 96,97\% | 1405786 | 16,52\% | 83,48\% | 1497609 | 9,99\% | 90,01\% | 2903395 |
| $65+$ | 1,28\% | 98,72\% | 4216465 | 5,39\% | 94,61\% | 6044415 | 3,70\% | 96,30\% | 10260880 |

Table 5: Presence or absence of labor or pension income as a function of age and gender.
Here, $Y$ is the sum of labor income and pension and rent income
4.2.2 about the French income tax, but applies to all taxes and benefits: being the second earner with a high revenue partner makes one directly lose eligibility to transfers like PPE, RSA, Family Complement, and so on. Table 12 in section 4.2 .6 shows the proportion of women among household's second earners, and women's average share in their household's labor income, for each fractile of households. Table 13 shows the corresponding effect on marginal income tax rates.

Of course, this needs not be the case: since all benefits and taxes are paid at the household level, their repartition between spouses is determined by a within-household bargaining. As outlined by Alesina et Al [2008], labor market participation itself is the result of a withinhousehold bargaining, meaning that the attribution of the roles of first and second earner is itself endogenous to this bargaining. One possible bargaining outcome would be that the second earner computes all the losses (benefit losses or additional amounts) she incurs because of the first earner's income, and asks the first earner to compensate her accordingly.

However, it can also be the case that second earner's income is considered as an "additional income", and that the first earner will demand to be compensated for all losses incurred by the household as a result of the second earner's activity. In this case, marginal rates of taxation faced by second earners are significantly raised. This is Rosen's (1977) idea.

The result is probably in between, depending on the bargaining power of spouses. In the rest of this study, we will focus on the second polar case: second earners are supposed to face the same marginal and average taxation rates as their household's.

## 4 Description of the existing devices

In the following section, we first describe French social security contributions and the corresponding differences between gross, net and taxable income. Then, we describe CSG and CRDS, which are two taxes computed on all individual gross incomes (including capital income and windfalls), directly deducted wherever possible, and which constitute a strong source of income for the State ( $75 \mathrm{Bn} €$ ). We then deal with income tax, which follows the principle of family income splitting, and approximately levied $59 \mathrm{Bn} €$ in 2008.

We then turn to PPE and RSA, two forms of benefits aimed at different (but overlapping) categories of people and providing very different features. PPE provided incentives to workers, while RSA provides a guaranteed minimum income that preserves incentives to work. We finally deal with children benefits, Family Allocations and Family Complement.

All these devices are then aggregated, and their features compounded, in the next section.

### 4.1 Gross, Taxable, Net : The various concepts of income

In this section, we describe both the way French labor income can be decomposed, and the way this decomposition was implemented in our simulator (which required some simplifications). We first describe the computation of gross wages versus net and taxable wages, and then the decomposition of other forms of labor income, like the income of non-salary earning workers, or replacement income.

### 4.1.1 Wages

As shown in section 3.5, wages are the most common case on the French labor market. A gross wage can be decomposed into three main amounts: social security contributions, CSG/CRDS taxes, and net income (or amount actually paid to the worker). This does not yet include income tax payments, which are in most cases not directly deducted from income. It should be noted that, in France, most social security contributions are made by the employer. These contributions are the difference between labor cost for the employer and gross wages. A possible future enhancement of the simulator would be to include these employer-side contributions as well.

This decomposition is particularly relevant to our simulator, since the various tax and redistribution devices address different income concepts. As can be seen on the decomposition of a $1000 €$ monthly salary in figure 1, CSG and CRDS address gross income, income tax and PPE address taxable income (whose computation we describe in the section below dedicated to income tax), and RSA addresses net, actually received income.

Figure 1: Social security contributions: decomposition of a $1000 €$ monthly salary

There are three main difficulties with this decomposition, and more precisely, with its implementation in the simulator:

- Social security contribution rates vary along two dimensions
- the level of income
- the status of the worker (executive/not executive, for instance)
- Although the biggest part of social security contribution is made of mandatory contributions, individuals or their employers can decide to contribute more than the

|  | base | rate |
| :--- | ---: | ---: |
| Health insurance, Maternity, Death | $R$ | $0,75 \%$ |
| Old-age insurance | $\min (R, P)$ | $6,65 \%$ |
| Addtional old-age contribution | $R$ | $0,1 \%$ |
|  |  | $\min (R, P)$ |
| Retirement contributions | $\min (R-P, 3 P)$ | $8,8 \%$ |
|  |  | $8,9 \%$ |
| Unemployment insurance |  | $2,4 \%$ |
|  |  |  |
| CSG | $0,97 R$ | $2,4 \%$ |
| non tax-deductible | $0,97 R$ | $5,1 \%$ |
| tax deductible |  |  |
| CRDS | $0,97 R$ | $0,5 \%$ |

Table 6: Social security and CSG-CRDS contribution rates of "non-executive" workers, 2008
$R$ is gross labour income; $P$ is the social security ceiling.
mandatory minimum, which increases the gap between their gross and net income. This is in fact a way for the state of allowing voluntary contributions to be tax exempt.

- The concept of "taxable income" does not coincide with anything economically meaningful. Its exact computation is described below, but the general rule is that social security contributions are tax deductible, and that only a part of CSG of contribution is tax deductible.

Globally, social security contribution rates slowly decrease with the level of income. Every year, the government releases a number called "social security ceiling" (plafond de la sécurité sociale), and the various social security contributions rates are computed (in a marginal rate schedule, like income tax), from brackets made of multiples of this value. In 2008, this value was $2773 €$ a month. It was increased to $2859 €$ in 2009. Table 6 shows contribution rates of "non-executive" workers, as a function of their level of income and of the social security ceiling.

| Taxable income (monthly) | Corresponding Gross income |
| :--- | ---: |
| $0 \leq R_{T}<P_{T}$ | $1.237 \cdot R_{T}$ |
| $P_{T} \leq R_{T}<3 P_{T}$ | $1.237 P_{T}+1.213\left(R_{T}-P_{T}\right)$ |
| $R_{T} \geq 3 P_{T}$ | $1.237 P_{T}+1.213 \cdot 2 P_{T}+1.095\left(R_{T}-3 P_{T}\right)$ |

Where $P_{T}=P / 1.237=2242 €$
Table 7: Formula used to infer gross income level from taxable income level
We call $P$ the social security ceiling (which is released in gross income terms) and $P_{t}$ its equivalent in taxable income. We call $R_{t}$ the taxable income observed in our data.

Simulation What we observe in the data is taxable income. Since we can not observe the status of the worker, we assume that all salary-earning workers are in the "not-executive" scheme. This is not realistic, but the two schemes are close enough for it to be a good approximation. As can be seen in the above table, if we assume that everyone follows the above scheme, then the function that transforms taxable income to gross income is a continuous and piecewise linear function, which can be described as this in table 7 .

Then, we simply apply the contribution scheme described in table 6 to infer social security contributions, CSG/CRDS contribution, and net (actually paid) income, which we then feed to our simulators of the various devices.

In the end, our goal is to leave social security contributions intact, but to replace CSG, CRDS, Income Tax, PPE, RSA, Children Benefits with one unified and simplified system.

### 4.1.2 Other types of income

Pensions Pensions are subject to the same social security contributions than wages, except pension contributions and a lower CSG contribution rate ( $-0,9$ percentage points, taken from the tax-deductible part of CSG).

Non wage earning worker's income Non wage earning workers are subject to the same mandatory contributions as wage-earning workers, but contribution rates and brackets are not the same and, more importantly, non wage-earning workers pay both the employee contributions and the employer contributions. There is variability within the category of non
wage-earning workers. Typically, small retailers are not subject to the same contribution rates than doctors of lawyers.

For now, in our simulator, we assume that contribution rates average the same than those of wage-earning workers. This amounts to putting all the variability of contribution rates on the employer-side, and recreating a "gross income" for non-wage earning workers that can be compared with those of wage-earning workers.

Replacement income In most cases, replacement income are subject to the same social security contributions that wages, but CSG tax rate is reduced by 1,4 percentage point (this reduction is taken from the tax-deductible part of CSG).

### 4.1.3 CSG and CRDS

CSG and CRDS are taxes created in 1991 and 1996, and that have bean regularly increased ever since. As of 2008, the CSG schedule is as follows:

|  | tax base | deductible CSG | non deductible CSG | CRDS |
| :--- | ---: | ---: | ---: | ---: |
| wages | $97 \%$ of gross | $5,1 \%$ | $2,4 \%$ | $0,5 \%$ |
|  | wage |  |  |  |
| pensions |  | $4,2 \%$ | $2,4 \%$ | $0,5 \%$ |
| replacement income | $6,7 \%$ | $3,8 \%$ |  | $0,5 \%$ |

Windfall and capital income are subject to higher rates.

### 4.2 Income Tax

The French income tax (impôt sur le revenu) is paid either monthly or every quarter, and its base is the taxable income (revenu imposable) of the previous year. In 2009, French taxpayers are paying income tax based on their 2008 income. Income tax is computed on a household basis: married couples, families with children, or couples bound by a PACS ${ }^{8}$ (Pacte Civil de Solidarité) file a joint declaration, and their tax amount depends on the sum of their individual incomes as well as of the structure of the family.

[^4]The concept of household used by the tax administration (one foyer fiscal is a group of people filing their tax declaration together) is not the same than the one commonly used, which is people actually living together. Indeed, when a child starts to work without leaving her parent's home, the family can decide between keeping her in the joint tax declaration, or filing two separate declarations (one for the child, the other for the family), depending on what results in the smallest overall tax amount. Hence, there are approximately $30 \%$ more income tax declarations than actual households. In 2006, there were approximately 35,5 millions tax declarations, and 26,4 millions households?

The overall tax return was $54 \mathrm{Bn} €$ in 2006, and close to $59 \mathrm{Bn} €$ in 2008.

### 4.2.1 Determination of taxable income

In this dissertation, we focus on the taxation of labor income, and leave taxation of capital income aside. For people earning salaries, the determination of taxable labor income is quite straightforward : most of the mandatory contributions to the social security system do not enter the tax base, with the exception of "not deductible CSG and CRDS", which approximately weigh $2,1 \%$ and $0,5 \%$ of gross labor income. For more detail about the computation of these two contributions, see section 4.1.3. Similar - but much more complex rules apply to independent workers, farmers, and very small businesses. They define different categories of income, and impose that deficits may only be taken away from incomes of the same category. Hence, if a person loses money on her commercial income (as a small retailer, for example), she still needs to pay a tax on her wage income, whatever the size of these losses. Large deficits can be deduced over several years of income. These rules have been taken into account in the simulator.

Generally, retirement benefits and unemployment benefits are taken into account in the tax basis. However, social minima, like the old-age minimum (minimum vieillesse, given to old people with very low retirement benefits), the guaranteed minimum income (revenu minimum d'insertion), and the new RSA, are not taken into account in the determination of taxable income.

[^5]Every worker receives a sheet from her employer or employers that gives her the exact amount of her taxable labor income. Then, every taxpayer is entitled to a $10 \%$ deduction on behalf of her professional expenses. Higher deductions are granted to people with higher expenses, if they provide a full record of these expenses.

To sum up, broadly speaking, in the case of wage earners with no capital income, income tax is computed on $90 \%$ of one's taxable income, which his itself roughly $81 \%$ of gross labor income. As explained in section 4.1, this $81 \%$ ratio tends towards $91 \%$ for very high incomes.

### 4.2.2 Computation of income tax amount: the logic of "Family Income Splitting"

The concept of family quotient The entire income tax system relies on the concept of "family quotient" (quotient familial), which is used to achieve family income splitting. It is defined as taxable income divided by a number of "shares" (parts de quotient familial), which depends on the family structure. This ratio is the amount that is eventually taken into account in the computation of tax rate.

$$
F Q=\frac{\text { taxable income }}{\text { number of shares }}
$$

The computation of the number of shares depends on many criteria, like the presence of a spouse, the number of children ${ }^{10}$, disability, or the fact of being a single-parent. In the general case, this number is computed as follows: singles are given one share, while couples are given two. Then, the couple's two first children each weigh 0.5 shares, and every other child weighs 1 share. In the case of single parents, the first child weighs 1 share, the second 0.5 , and every other child weighs 1 share. Figure 8 summarizes the general case :

Particular cases include widows, that have the same FQ they had when their partner was alive. An additional 0,5 share is also given to every dependent that satisfies one or several of the following criteria:

- disabled dependent

[^6]| family situation | number of children |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | 0 | 1 | 2 | 3 | 4 | additional child |
| single | 1 | 2 | 2,5 | 3 | 4 | +1 |
| couple | 2 | 2,5 | 3 | 4 | 5 | +1 |

Table 8: Determination of the number of shares used in the computation of income tax.

- wounded veterans
- veterans over 75

This means that if a family has two people satisfying these criteria, it is given 1 entire additional share, and so on. However, the fact that one person enters into several categories does not change the amount of half shares she receives: it is limited to one half share per person.

Computation scheme Once the number of shares is computed, the tax rate is computed as follows:

$$
\text { Tax }=f\left(\frac{\text { taxable income }}{\text { number of shares }}\right) \cdot \text { number of shares }
$$

The function $f$ being defined through a marginal rate scheme, described in table 9:

| Portion of income | Tax levied on this portion of income |
| :--- | ---: |
| $0-5852$ | $0 \%$ |
| $5852-11673$ | $5,5 \%$ |
| $11673-25926$ | $14 \%$ |
| $25926-69505$ | $30 \%$ |
| 69505 and above | $40 \%$ |

Table 9: Income tax scheme of 2009
Example 1: a single person earning $15000 €$ a year pays the following amount:

$$
\text { Tax }=5852 \cdot 0 \%+(11673-5852) \cdot 5,5 \%+(15000-11673) \cdot 14 \%=786 €
$$

Example 2: A couple earning $30000 €$ a year pays the following amount:

$$
f\left(\frac{30000}{2}\right) \cdot 2=786 \cdot 2=1572 €
$$

As can be seen with these examples, the French income tax system provides strong incentives to marriage, as opposed to others, where the existence of a " marriage tax " is a
concern [Alm et al, 2004]. This has been a major argument for the implementation of the PACS, a contract allowing couples (including same-sex couples) to benefit from this system under less strict conditions than regular marriage. This system provides potentially strong subsidies to marriage and children, that are increasing with the level of income. The "marriage subsidy ${ }^{11}$ " is not bounded, but the "children subsidy" is limited to $2292 €$ per children-related share. For example, if a couple has two children (each weighing 0,5 shares in the current system), the difference between the amount that would be paid if the couple had no children and the amount that is actually paid can not exceed $4584 €$.

Figure 2 shows the tax amount paid as a function of taxable incom\& ${ }^{12}$, between singles and couples. It shows that if income is kept constant, a couple pays much less income tax than a single.

Figure 3 shows the tax amount paid as a function of taxable income and the number of children. We can see that, as explained above, the children-related tax deduction is increasing in the level of income, but bounded above by $2292 €$ times the number of children-related shares. We deal with the issue the gains resulting of the presence of children, in all studies devices, in section 5.4 .

### 4.2.3 Additional tax reduction for low income households (décote)

After the theoretical tax amount $T^{\prime}$ has been computed, if the amount due is lower than $862 €$, an additional tax reduction is granted (décote), which amounts to the difference between 431 and half the theoretical tax amount.

$$
T=T^{\prime}-\left(\frac{862}{2}-\frac{T^{\prime}}{2}\right)
$$

Effects and side-effects of this additional tax reduction are shown in section 4.2.5,

[^7]

Figure 2: Income tax as a function of household taxable income, for singles and couples without children

### 4.2.4 Average contribution rates

Table 4 shows average contribution rates by fractile of household income. We compute each household's contribution, with and without children. Note that the amounts we present here correspond to what we described above, which is not exactly equal to what taxpayers actually pay, because we did not take into account the numerous tax deductions. As opposed to professional expenses, which are deducted from taxable income, tax reductions are directly deducted from the due tax amount. For example, a $100 €$ donation to a charity results in a $60 €$ reduction in due income tax. There is a large number of such specific tax reductions, which we do not yet include in the simulator because of their simplicity. This should however be done in future research, since tax reductions are important as well in terms of households enjoying them ( 13,7 Millions in $2007^{13}$, as in terms of the amounts

[^8]

Figure 3: Income tax paid by couples as a function of taxable income and number of children
involved ( $20,7 \mathrm{Bn} €$ were subject to such partial deductions in the same year $\sqrt{14}$.
In this table (4), one can see two main effects: first, the tax reduction provided by the presence of children can be significant: it represents, on average, about $4000 €$ for the richest $0,1 \%$ of the population (in terms of labour income). We can also see that these gains are strongly increasing with income.

This table also illustrates how progressive the current income tax system is: most deciles have a very low average contribution rate, and this rates only shows a strong increase at the very top of the income distribution: fractile $99-99.9$ has an average contribution rate of $16,7 \%$ (of gross labour income), whereas fractile $99.9+$ has a $28,9 \%$ contribution rate, which would correspond to the nominal $40 \%$ tax rate if it was expressed as a funciton of net taxable labor income, and not of gross labor income.

[^9]However, it should be noted that this device coexists with other devices that are neither progressive (like CSG) nor providing children benefits that increase with income (like RSA, PPE, or Family allocations and family quotient). This is what makes a more global analysis necessary, in order to see what effects are dominating, once all devices work together. This is done in section 5 ,

| fractile of households | $P_{f}$ | gross labour income | taxable income | income tax | income tax (no children) |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | 29994 | 21698 | 1558 | (5,2\%) | 1861 | (6,2\%) |

| 90-95 | 59090 | 66689 | 48293 | 4089 | (6,1\%) | 4926 | (7,4\%) |
| 95-99 | 76863 | 95842 | 70708 | 8948 | (9,3\%) | 11030 | (11,5\%) |
| 99-99.9 | 135141 | 179090 | 139204 | 29932 | (16,7\%) | 33534 | (18,7\%) |
| 99.9+ | 309114 | 535518 | 454097 | 154927 | (28,9\%) | 158825 | (29,7\%) |
| Sum (all, Bn€) |  | 1064,9 | 770,4 | 55,3 |  | 66,1 |  |

Figure 4: Average contribution rates by fractile of households, income tax, 2009 scheme
Average tax rates are expressed as a function of gross labor income, which explains why they do not tend towards the nominal $40 \%$ on top fractiles.

### 4.2.5 On the residual marriage penalty

As can be seen in the décote formula above, the number of people living in a household, which is otherwise taken into account for income splitting, does not appear in the computation of the décote. This leads to a small but sometimes significant marriage penalty, since two people earning the same income and enjoying a deduction on behalf of décote stop receiving that deduction if they decide to get married (and hence to file jointly). Table 10 shows a simulation of this marriage penalty in the case of spouses earning the same income:

| gross <br> income | base tax* | individual <br> décote | resulting <br> tax | couple <br> decote | resulting <br> tax | marriage <br> penalty |
| ---: | ---: | ---: | ---: | ---: | ---: | ---: |
| 8000 |  |  |  |  |  |  |
| and below | 0 | 414 | 0 | 414 | 0 | 0 |
| 9000 | 80 | 394 | 0 | 373,5 | 0 | 0 |
| 10000 | 162 | 373,5 | 0 | 333,5 | 0 | 0 |
| 11000 | 242 | 353,5 | 0 | 293 | 0 | 0 |
| 12000 | 322 | 333,5 | 0 | 253 | 69 | 69 |
| 13000 | 402 | 313,5 | 0 | 212,5 | 190,5 | 190,5 |
| 14000 | 484 | 293 | 0 | 172,5 | 310,5 | 310,5 |
| 15000 | 564 | 273 | 18 | 132 | 432 | 414 |
| 16000 | 650 | 251,5 | 147 | 89 | 561 | 414 |
| 17000 | 854 | 200,5 | 453 | 0 | 855 | 402 |

| 20000 | 1470 | 46,5 | 1377 | 0 | 1469 | 92 |
| 21000 |  |  |  |  |  |  |
| and above | 1674 | 0 | 1674 | 0 | 1674 | 0 |

Table 10: Marriage penalty and marriage subsidy
This table compares, for several levels of gross income, the income tax paid by a couple formed of two individuals earning exactly the same income to sum of the individual taxes paid by the same people if they do not file jointly.

* In the case of two people earning the same income, "base tax" (which corresponds to income tax obtained by applying $f$, before applying the décote) is the same, whether they file jointly or not.

If two people A and B earn the same gross income $Y_{G}$, then the marriage penalty amounts to:

$$
T\left(2 Y_{G}, 2\right)-2 \cdot T\left(Y_{G}, 1\right)
$$

Where T is the income tax function described above in this section (as $f$ ), its first argument is the gross income, and its second the number of people then income is split between. This is the computation presented in the last column of table 10 , as well as in figure 5 .

Figure 5: Marriage penalty of same-income couples, as a function of gross individual income.

Of course, the results change a lot when there is a strong income gap between spouses, because the effect of income splitting dominates the effect of décote. Hence, table 11 estimates marriage penalty and marriage gains actually faced by French households, given their respective income decompositions (without taking into account the additional incomesplitting effect of children), on 2006 ERFS data (in 2008 value and with the 2009 tax schedule):

Again, joint filing is mandatory (and generally beneficial) for married or PACS couples, so there is no flexible way for a household to switch from joint filing to individual filing.

| marriage <br> penalty | number <br> of households | average <br> penalty |
| :---: | ---: | ---: |
| negative | $10,3 \mathrm{M}$ | $-935 €$ |
| positive | $2,4 \mathrm{M}$ | $162 €$ |

Table 11: Computation of marriage penalty and marriage gains among joint files
This table compares the amount paid by couples (without the effect of children) to the amount these couples would pay if they filed separately.

### 4.2.6 The effects of joint filing on individual marginal tax rates

The main advantage of the current income tax design is that it makes it very straightforward for taxpayers to know their marginal tax rate. However, the fact that it is organized around joint filing and family income splitting can also lead to substantial increases in marginal tax rate of household's second earners.

For example, a woman earning a gross labor income of $10000 €$ per year faces a $10 \%$ marginal tax rate if she lives alone, but a $40 \%$ if the sum of her income and her husband's reaches the fourth tax bracket. Otherwise stated, in the French income tax system, joint filing is almost always profitable from the point of view of the household in terms of average tax rate, but provides strong disincentives to work to second earners. Given that second earners are, most of the time, women (see table 12 for an illustration on French ERFS data), and that women's labor supply is known to be more sensitive to taxation than men's, this leads to a substantial distortion as regards the labor supply of women, and possibly strong efficiency losses.

Table 13 shows, for married couple with positive income and without children, the average marginal rate of income tax of the household, and then the contrafactual average marginal tax rate that each spouse would face if they had filed their income declaration separately. The striking fact is that in most cases, joint filing leads to a reduction in the marginal tax rate faced by the man, and in a rise in the marginal tax rate faced by the woman.

If we accept that women's labor supply have a higher sensitivity to taxation than men's, then this goes against the Ramsey criterion for optimal taxation, that implies people with

| fractile <br> (first <br> earner) | fractile <br> lower <br> limit | fractile average <br> first earner <br> labor income | part of the second <br> earner in <br> household income | proportion of <br> women among <br> second earners |
| :--- | ---: | ---: | ---: | ---: |
| All |  | 27835 | $27,14 \%$ | $81,65 \%$ |
| $0-10$ | 5 | 6936 | $28,98 \%$ | $78,49 \%$ |
| $10-20$ | 10305 | 12500 | $29,41 \%$ | $81,16 \%$ |

Table 12: Couples with positive labor income: share of second earner's taxable labor income in total household labor income and proportion of women among second earners, ranked by fractile of labor income of the first earner.
a higher labor supply elasticity with respect to taxation (here, women) should face lower marginal tax rates than people with a lower elasticity (men).

We will come back to this phenomenon in the next section of our study, in which we compute marginal tax rates taking into account more taxes and the most significant benefits.

### 4.3 PPE

The PPE (Prime Pour l'emploi, which could approximately translate to Subsidy for Employment), is a device aimed at reducing tax rates on lower income workers, providing higher incentives to enter the labor market or to raise one's labor supply. It was introduced in 2001 by the left-wing government of Lionel Jospin, and was extended by right-wing governments since then.

It is to be paid in $201 q^{15}$ to people who worked in 2009. However, people who find themselves in difficult conditions, like people currently exiting unemployment, can be paid

[^10]| fractile | $P_{f}$ | $Y_{m}$ | $Y_{w}$ | share of the woman | $R_{h}$ | $R_{w}$ | $R_{m}$ |
| :--- | ---: | ---: | ---: | ---: | ---: | ---: | ---: |
| All |  | 23445 | 10807 | $31,55 \%$ | $15,4 \%$ | $12,2 \%$ | $18,7 \%$ |
| $0-10$ | 0 | 6650 | 1998 | $23,10 \%$ | $0,0 \%$ | $0,2 \%$ | $0,7 \%$ |
| $10-20$ | 13418 | 11601 | 3969 | $25,49 \%$ | $0,1 \%$ | $1,7 \%$ | $8,3 \%$ |
| $20-30$ | 17518 | 14842 | 4432 | $22,99 \%$ | $5,1 \%$ | $2,0 \%$ | $11,8 \%$ |
| $30-40$ | 21126 | 17046 | 5947 | $25,86 \%$ | $7,4 \%$ | $2,5 \%$ | $12,4 \%$ |
| $40-50$ | 24886 | 18777 | 8093 | $30,12 \%$ | $14,1 \%$ | $4,9 \%$ | $13,0 \%$ |

| $99.9+$ | 292832 | 465240 | 81073 | $14,84 \%$ | $36,0 \%$ | $33,9 \%$ | $35,9 \%$ |

Table 13: The issue of second earners: actual and contrafactual marginal tax rates of second earners

Married couples with positive income and without children (approx 6 Millions households).
$\left(Y_{w}\right)$ : average share of the woman's income in household labor income $\left(Y_{w}+Y_{m}\right)$
$\left(R_{h}\right)$ : marginal tax rate of the household, $\left(R_{w}\right)$ : marginal tax rate the woman would face if was single.
$R_{m}$ is the marginal rate the woman's husband would face if he was single.
$P_{f}$ gives the lower bound and each fractile.

Note: the theoretical $40 \%$ marginal rate is never reached because of the $10 \%$ deduction on behalf of working expenses.
Note 2: A methodological explanation about the computation of these average marginal rates is available in section $H$ of the appendix.

The fractiles presented here are fractiles of households (couples).
an advance on their PPE amount (400€) directly in 2009, and the remainder in 2010.
The PPE system is considered complex, because it mixes criteria about household global income with criteria about individual income. More specifically, the biggest part of PPE is computed taking into account individual income only, but eligibility conditions are checked against household income, and there exist specific increases that depend on the family structure that are granted at the household level.

### 4.3.1 Eligbility conditions

In order to be eligible to PPE, workers must belong to a household whose overall taxable income does not exceed $16251 €$ for singles, and $32498 €$ for couples. This amount is increased by $4490 €$ for each additional fiscal half part of the household ${ }^{16}$. This is one of the reasons that leads young workers to leave their parent's fiscal household: not doing so makes them lose eligibility to PPE benefits.

### 4.3.2 Base PPE benefit

If a household satisfies the above eligibility conditions, PPE benefits are computed individually, for every worker's labor income, and then summed up and paid at the household level. The logic is, in a way, similar to the "Family Quotient", because benefits are computed on the basis of "full-time equivalent" income. If a person does not work full time, then her income is first converted to full time income, and the PPE formula is then applied to the full-time equivalent amount, as shown below:

$$
P P E=g\left(\frac{Y_{L}}{\alpha}\right) \cdot \alpha
$$

where $\alpha=1$ if the person works full time, 0.5 if she works half time, and so on ${ }^{17}$. The exact computation of $\alpha$ is described in section D. 1 of the appendix.

Then, the function $g$ is defined as shown in table 14 ,

[^11]| Family situation | $R$ | PPE Base Benefit |
| :--- | ---: | ---: |
| single people <br> or couples where <br> partners are both <br> working <br> or households with <br> one dependent <br> earning more than 3 <br> 743€ a month | $12475 \leq R<17451$ | $R \cdot 7,7 \%$ |
|  |  | $(17451-R) \cdot 19,3 \%$ |
| Couple where only <br> one person <br> is working | $3743 \leq R<12475$ |  |
|  | $12475 \leq R<17451$ | $(17451-R) \cdot 19,3 \%+83 €$ |
| $17451 \leq R<24950$ |  |  |
| $24950 \leq R<26572$ | $83 €$ |  |
| Single parents <br> (parents isolés) <br> and special cases | $3743=R=12475$ | $(26572-R) \cdot 5,1 \%$ |

Table 14: Determination of PPE base benefits
$R$ is the "full-time equivalent" individual labor income:

$$
R=\frac{Y_{L}}{\alpha}
$$

In the simplest case (single full-time worker) this results in the base benefit function, shown in figure 6. As can be seen, the fade-in/fade-out construction leads to ambiguous effects of implicit marginal rates of taxation. A person whose yearly full-time equivalent income is below $17451 €$ faces a negative implicit marginal rate of taxation ${ }^{18}$, of $-7,7 \%$, while a person earning more faces a $19,3 \%$ marginal rate of implicit taxation.

Figure 6: PPE formula in the simplest case (full-time worker)

### 4.3.3 Increases (Majorations)

One the base PPE benefit is computed, a few increases, given once at the household leve ${ }^{19}$, can apply depending on the level of income and the family structure. Generally, they provide a small lump sum benefit on behalf of each dependent of the household. After a certain level of income, it becomes a small lump-sum that no longer increases in the number of dependents. Table 15 summarizes the schedule:

[^12]| Family situation | R | Increase |
| :---: | :---: | :---: |
| single people <br> or couples where partners are both working and households with one dependent earning more than $3743 €$ a month | $3743 \leq \mathrm{R} \leq 12475$ |  |
|  | $12475<\mathrm{R} \leq 17451$ |  |
|  |  | $36 €$ |
|  |  | per dependent |
| Couple where only one person is working | $3743 \leq \mathrm{R} \leq 12475$ |  |
|  | $12475<\mathrm{R} \leq 17451$ |  |
|  | $17451<\mathrm{R} \leq 24950$ | $36 €$ |
|  | $24950<\mathrm{R} \leq 26572$ | per dependent |
| Single parents and special cases (parents isolés) | $3743 \leq \mathrm{R} \leq 12475$ | $72 €$ for the first |
|  |  | dependent |
|  | $12475<\mathrm{R} \leq 17451$ | and 36 for the others |
|  | $17451<\mathrm{R} \leq 26572$ | $72 €$ |

Table 15: Schedule of PPE increases
These increases are granted once, at the household level

### 4.3.4 Simulation results

Table 16 presents a comparison between the aggregates found in the simulation and known 2008 PPE data. The computation of PPE spendings is quite accurate (with a 0,1 million precision) but the number of concerned households we find is slightly off. This might be due to the fact that the only data available are 2006 data: a more precise actualization to 2008 value could reduce this gap.

A more thorough analysis of the effects of this device on marginal rates of taxation, and more importantly of its interaction with RSA will be presented in section 5 .

As can be seen in figure 6, PPE does not address the bottom of the income distribution, since people earning less than $3743 €$ (typically the income of people working around $30 \%$ time at minimum wage). These people are much more concerned by the device we describe next, the new guaranteed minimum income, or RSA.

| fractile | $P_{f}$ | \# Eligible <br> households | PPE benefits <br> (Billions) |
| ---: | ---: | ---: | ---: |
| All |  | $\mathbf{8 3 1 8 ~ 9 6 9}$ | $\mathbf{4 , 6}$ |
| $0-10$ | 0 | 384946 | 0,1 |
| $10-20$ | 5428 | 1821218 | 0,9 |
| $20-30$ | 11693 | 1646810 | 1,2 |
| $30-40$ | 16069 | 1993275 | 1,1 |
| $40-50$ | 19474 | 706091 | 0,3 |
| $50-60$ | 22984 | 447937 | 0,2 |
| $60-70$ | 27373 | 653656 | 0,4 |
| $70-80$ | 33639 | 665012 | 0,4 |
| $80-90$ | 43002 | 0 | 0 |
| $90-95$ | 59090 | 0 | 0 |
| $95-99$ | 76863 | 0 | 0 |
| $99-99.9$ | 135141 | 0 | 0 |
| $99.9+$ | 309114 | 0 | 0 |

Table 16: Summary statistics on our PPE computation
$P_{f}$ is the lower limit of the fractile, expressed in gross income
We find an aggregate amount of $4,58 \mathrm{Bn} €$ on behalf of PPE, which corresponds to actual 2008 PPE spendings, and 8,3 Millions of households benefiting from PPE benefits, which is a bit less than the actual number $(8,9 \mathrm{M})$

### 4.4 RSA

The RSA Revenu de solidarité active is a device that replaces the existing Guaranteed minimum income (RMI), bringing several economic improvements in terms of incentives to labor supply.

### 4.4.1 The Minimum Guaranteed income

The first version of the Guaranteed minimum income had been designed in 1988 for approximately 400000 people, and has grown inadequate for the $1,2 \mathrm{M}$ people who were receiving its benefit in the 2000s.

The most frequent critique that was put forward against it was the disincentives to labor supply that it produced. Indeed, it was at first conceived as a supplemental income that would allow every beneficiary to reach a certain level of income (454,63€ as of 2009), an its potential as an inactivity trap was first not taken into account. Its base formula of the RMI was the following:

$$
R M I=C_{F} \cdot \bar{Y}-Y \quad \forall Y<\bar{Y}
$$

Where $\bar{Y}$ is the guaranteed minimum level of income, and $Y$ is the beneficiary's other income. $C_{F}$ is a coefficient that depends on the family situation. It is above 1 , and increases with the presence of a spouse and the number of children. This means that, for small variations in income, the implicit marginal tax rate faced by the beneficiary is $100 \%$ :

Let $Y_{T}$ be one's total income (RMI included): $Y_{T}=R M I+Y$. So in the case of a person having no labor income, entering the labor market and earning an amount less than $\bar{Y}$ yields, in the end, the same total income $Y_{T}^{\prime}=\left(R M I_{0}-\Delta Y\right)+(Y+\Delta Y)=Y_{T}$. All of the increase in income is swallowed by a reduction in benefit amount.

Various measures existed, in order to counteract this effect : temporary measures (intéressement, and then prime de retour à l'emploi) allowed beneficiaries to accumulate their benefits and their labor income for a few months, hence facilitating the transition back to activity. However, this temporary effect was criticized for not being strong enough, because when averaged over several years, marginal rates of implicit taxation induced by the RMI
system were still very high.
Another set measures existed, that gave beneficiaries the obligation to actively search for a job, and to respect an individual "insertion contract". This set of rules still applies to the new system.

### 4.4.2 The new system and its reduction of marginal rates

The new system, introduced in mid 2009 and called RSA, yields an in-depth reform on the RMI, in the sense that marginal rates of implicit taxation is directly taken into account in the computation formula, and chosen every year by a government decision.

As of 2009, the formula is as follows :

$$
R S A=\max \left(0, \bar{Y} \cdot C_{F}-\beta Y_{L}-Y_{O}\right)
$$

where $\bar{Y}$ is the same amount as in the old system (454,63€ in 2009), $Y_{L}$ is one's labor income, $Y_{O}$ is one's other sources of income, and $C_{F}$ is a coefficient above 1, depending on the household family situation. The rate $\beta$ is, as of 2009 , of $38 \%$.

Table 17 shows the formula according to which $C_{F}$ is determined.

| situation | $C_{F}$ |
| :--- | ---: |
| Single person | 1 |
| First dependant (spouse or firstchild) | $+0,5$ |
| Second dependant | $+0,3$ |
| Third Dependant | $+0,3$ |
| Additional dependant | $+0,4$ |
| Single parents * | 1,284 |
| Each child | $+0,428$ |

Table 17: Determination of RSA base benefit as a function of family situation
Exemple : a couple with two children has a coefficient of $1+0,5+0,3+0,3=2,1$
*See the note about the category "single parent" below

Contrary to what happened with the previous system, an increase in labor income from 0 to $100 €$ a month yields an increase of end-of-the-month total income by $100(1-\beta)=62 €$.

This is is still a low retention rate (as we show in section 5, it is comparable to retention rates on very high and heavily taxed incomes), but is still much better than the previous $0 \%$.

The "other income" category, denoted above as $Y_{O}$, includes all sources of income that are not linked to labor, and are hence subject to a $100 \%$ deduction of RSA benefits. This the case for capital income or family benefits, but also for all social minima. This $100 \%$ deduction of other social minima is very useful for our simulation, since it makes the issue of unobserved social minima income less problematic for the realism of our RSA simulation. This issue is discussed in the next subsection (4.4.3).

Full deduction is also the rule for a part of housing benefits received by households. The part of housing benefits that is deducted from RSA benefits is fixed every year under the name of forfait logement, and depends on the family situation according to the scheme presented in table 18 .

Note about the "single parent" status:
The status of "single parent" does not apply to every person that is single and has children. In order to be considered as a single parent (and receive the benefits that are linked to this status), one needs to fulfill the following criteria:

- Have at least a child (or be pregnant)
- File one's tax declaration as single.
- Not live with a partner (even unofficial; controls are in principle possible.)

| Family situation | Housing Deduction <br> forfait logement |
| :--- | ---: |
| Single person | $54,56 €$ |
| Couple without children, or single parent with one child | $109,11 €$ |
| Other situations | $135,03 €$ |

Table 18: Deduction on behalf of housing benefits (forfait logement)

### 4.4.3 RSA Simulation results

Table 19 presents the results of our RSA simulation. We find a total spending of $19,78 \mathrm{Bn} €$, which is much higher than the amount announced by the government (approximately

Figure 7: RSA benefits for individuals and couples as a function of labor income.
Note: each additional child shifts this curve up by an amount comprised between 136 and $181 €$, depending on the total number of children that the family has, as described in table 17. Single parents have higher benefits than what is shown above.
$10 \mathrm{Bn} €)$ : this is not surprising, since there are many other benefits that we did not simulate here, which account for a large amount of unobserved income at the bottom of the distribution, and that are deducted from RSA benefits at a $100 \%$ rate.

The previous minimum guaranteed income used to cost $6,18 \mathrm{Bn}$, and other unobserved allocations, like API (for isolated parents, 1,07 Bn), AAH (for disabled adults, 5,50 Bn), PIRE (for people reentering the labor market, $0,5 \mathrm{Bn}$ ) account for a part of the 10 Bn $€$ difference between our projections and government aggregates. The remainder of the difference $(2,8 \mathrm{Bn})$ is probably due to other unobserved income, like the income of people who do not file an income declaration.

The consequence of this gap in our simulation is probably not too important in terms of redistribution, because it mostly corresponds to benefits, which simply are given through other devices than RSA. However, in terms of marginal retention rates, this probably leads to an overestimation of the proportion of people who face a $38 \%$ marginal rate of taxation at the bottom of the distribution. (for example, AAH benefits still result in higher implicit marginal tax rates (that vary with the level of labor income).

One effect of the new RSA formula (as compared to the old Minimum Guaranteed Income formula) is to strongly increase the number of households that become eligible to benefits. Indeed, in the previous system, eligible people needed to have an increase less than $\bar{Y}$, whereas with RSA, households between $\bar{Y}$ and $\bar{Y} / 0,38$ are also eligible to a portion of RSA benefits.

Households that were eligible to the previous system are called "base" (socle), and the others, that have become eligible because of the new formula, are called "hat" (chapeau) beneficiaries. Table 20 shows the decomposition of spendings between these categories.

Our computation of "hat" RSA is comparable to government previsions (4,3 Bn vs 3,3 according to the Senate). It is our our computation of "base" RSA that is much too high (more than twice as high) which comforts the hypothesis that missing revenues are indeed social minima.

Since we work on raw tax declarations, another part of the explanation is the fact that people whose situation change (when they marry or divorce, for instance) are required to file several income tax declarations for the same year. Hence, we can see some of them as two

| QTIL | $P_{f}$ | gross labor <br> income | average RSA <br> benefit | total RSA <br> spendings |
| ---: | ---: | ---: | ---: | ---: |
|  |  | $\mathbf{2 9 9 9 4}$ | $\mathbf{5 5 7}$ | $\mathbf{1 9 , 7 8} \mathrm{Bn}$ |
| $0-10$ | 0 | 1442 | 3427 | $12,17 \mathrm{Bn}$ |
| $10-20$ | 5428 | 8866 | 1219 | $4,33 \mathrm{Bn}$ |
| $20-30$ | 11693 | 13972 | 464 | $1,65 \mathrm{Bn}$ |
| $30-40$ | 16069 | 17847 | 234 | $0,83 \mathrm{Bn}$ |
| $40-50$ | 19474 | 21168 | 171 | $0,61 \mathrm{Bn}$ |
| $50-60$ | 22984 | 25076 | 54 | $0,19 \mathrm{Bn}$ |
| $60-70$ | 27373 | 30306 | 0 | $0,00 \mathrm{Bn}$ |
| $70-80$ | 33639 | 37997 | 0 | $0,00 \mathrm{Bn}$ |
| $80-90$ | 43002 | 50100 | 0 | $0,00 \mathrm{Bn}$ |
| $90-95$ | 59090 | 66689 | 0 | $0,00 \mathrm{Bn}$ |
| $95-99$ | 76863 | 95842 | 0 | $0,00 \mathrm{Bn}$ |
| $99-99.9$ | 135141 | 179090 | 0 | $0,00 \mathrm{Bn}$ |
| $99.9+$ | 309114 | 535518 | 0 | $0,00 \mathrm{Bn}$ |

Table 19: RSA simulation results: average and total RSA given to households, for each fractile

All households are included in these computations, but only people over 25 are eligible.

|  | Number of households | Total spendings |
| ---: | ---: | ---: |
| Households with 0 labor income | $1,35 \mathrm{M}$ | $7,47 \mathrm{Bn}$ |
| "Base" (except 0-income households) | $2,02 \mathrm{M}$ | $7,98 \mathrm{Bn}$ |
| "Hat" | $3,40 \mathrm{M}$ | $4,32 \mathrm{Bn}$ |
| All beneficiaries | $6,65 \mathrm{M}$ | $19,77 \mathrm{Bn}$ |

Table 20: RSA simulation results: number of households and corresponding spendings
distinct fiscal households who are both eligible to RSA, when we are indeed dealing with a person whose overall yearly income does make her eligible. This is a potentially strong source of RSA overestimation, and, perhaps more than the ones named above, of biases. Fixing this problem could be an important improvement of the simulatorin the future.

In the end, our reproduction of RSA is not perfect, but it seems sufficient for our purpose.

### 4.5 Family and Children benefits

As the previous sections have shown, many French taxation or redistribution devices deal with family (the presence of a spouse or of children), in one way or another. However, there also exist specific transfers directly aimed at families, that common language regroups under the expression of "family allocations" (allocations familiales).

These family benefits include two main components:

- "family allocations" (allocations familiales), which only depend on the number and the age of children, and not at all on the number of income.
- "family complement" (complément familial), only available to families below a certain level of income and with three children or more.

These transfers are computed and paid by a specialized government organism, called CAF (Caisse des Allocations Familiale $\sqrt[207]{20}$.

### 4.5.1 Family Allocations (allocations familiales)

Family allocations consist in a base benefit that depends on the number of children (described in table 21), and of an increase ${ }^{21}$ (majoration) that depends on their age and their year of birth ${ }^{22}$.

| Number of children (under 20) | Monthly base benefit |
| ---: | ---: |
| 1 | $0,00 €$ |
| 2 | $123,92 €$ |
| 3 | $282,70 €$ |
| Additional child | $+158,78 €$ |

Table 21: Family allocations before increases, as of January $1^{\text {st }}, 2009$

## Base benefit

[^13]Increases (majorations) For families with two children or more, the following increases apply:

- For Children born before may $1^{\text {st }}, 1997$ :
$-+34,86 €$ for every child between 11 and 16.
- +61,96€ for every child between 16 and 20.
- For children born after this date, there is a single increase of $34,86 €$ for children over 14.23

Note that in the case of family with two children only, no increase is granted on behalf of the oldest child.

### 4.5.2 Family complement (complément familial)

The Family complement is a lump sum transfer, given to families with three children or more, under certain conditions on household income. As of 2009, the amount of the family complement is $161,29 €$. Conditions on income are described in table 22. If the family's income is higher than the limit of eligibility by less than $1869,84 €$, a part of the complement is still granted ${ }^{24}$.

| Number of <br> children | Couples with only one <br> worker | single parents or two active <br> parents |
| ---: | ---: | ---: |
| 3 | $34489 €$ | $42191 €$ |
| 4 | $40237 €$ | $47939 €$ |
| additional child | $+5748 €$ | $+5748 €$ |

Table 22: Maximum family income that triggers eligibility to the Family Complement, as of 2009

### 4.5.3 Aggregates

In 2007, the CAF spent a total $12,3 \mathrm{Bn} €$ on behalf of Family Allocations, and $1,6 \mathrm{Bn} €$ on behalf of the Family Complement. There are other specific direct transfer ${ }^{25}$ in provided

[^14]to families with children, the two most important of which being the allocation de rentrée scolaire, given to families at the beginning of academic years on behalf of school expenses, and the allocation de soutien familial, given to single parents and adopters. These other transfers represent a total of $5 \mathrm{Bn} €$.

### 4.6 The timing of tax and benefit calculation and payment

|  | $T_{Y}$ | $T_{R}$ |
| :--- | ---: | :--- |
| Income Tax | 2008 | 2009 |
| CSG/CRDS | 2008 | 2008 (deducted from monthly wages) |
| PPE | 2008 | 2009 (advance in 2008 for people exiting |
|  |  | unemployment) |
| RSA | 2008 | 2008 (on the previous quarter) |
| Family Benefits | 2008 | 2008* |

Table 23: Timing of tax and benefits calculation and payments
$T_{Y}$ is the year of revenue on which the tax is levied or the benefit computed. $T_{T}$ is the year on which the tax or benefit is actually paid.

* As explained in section 4.5, most of children benefits do not depend on income, but solely on the number of children.

## 5 Reproducing the existing system: economic features

### 5.1 Average contribution rates and redistributive features

Now that we have described devices one by one and seen their somewhat ambiguous effects (for example as regards the treatment of children), this section presents the overall economic features they provide when put together.

We first present a few simple cases, in which we draw and decompose the "tax curve" that results from compounding all studied devices, both for singles and for couples. We then study average contribution rates, both at the household level and at the individual level. We finally study marginal tax rates, both at the household level and at the individual level. What
we call "tax rates" are both implicit and explicit tax rates, whether they are actual paid taxes or losses in benefits. These are equivalent in terms of their effect on labor supply decision.

Household level analysis is quite straightforward, but analysis at the individual level requires a few hypotheses about the repartition of taxes and transfers among household members. This repartition is likely differ whether we are considering average tax rates or terms of marginal tax rates, when one household member decides to change her labor market participation. These hypotheses are presented below.

### 5.1.1 Tax and Benefit curves in simple cases

Figures 8 and 9 represent the average tax rates faced by singles and couples without children in the simplest case, which is people over 25 and not retired, not disabled, not unemployed, and that do not have any children-related or special tax exemption or transfer of any kind. It is also assumed that they do not have any capital income. The curves describe implicit tax rates faced by such (full-time) workers, as a function of gross labor income.

Our overall tax rates compound:

- Income Tax
- CSG \& CRDS
- PPE Benefits
- RSA Benefits
- Family Allocations and Family complements

However, social security contributions are not included in this overall tax rate. Indeed, they are not actual taxes, in the sense that the benefits they give right to are proportional to contributions.

Most of the kinks in the bottom of the overall tax curve are due to the PPE schedule and its eligibility boundaries. At the top, kinks are due to the variation of the ratio between gross labor income and taxable income that happens when the "social security ceiling is reached" (around $32000 €$ a year for a single worker). As gross labor income tends to infinity, the current overall tax rate (for singles or couples without children) tends to $40,8 \%$, that can be

Figure 8: [Singles]Implicit and explicit taxes as a function of gross labor income.
These curves are computed for single people (men or women), with no children, and whose income is $100 \%$ salary. For PPE computation, these people are assumed to work full time.
decomposed as follows: $33 \%$ of income tax and $7,8 \%$ of RSA. PPE and RSA benefits are of course of $0 \%$. The limit rate of current income tax rate, as income tends to infinity, is $33 \%$ and not $40 \%$, because we express everything in terms of gross income, and not in terms of taxable income. See section 4.1 for more details about this issue.

Figure 9: Implicit and explicit taxes as a function of gross labor income.
These curves are computed for couples with no children, and whose income is $100 \%$ salary. For PPE computation, these people are assumed to work full time.

The same curves, but expressed in terms of tax rates rather than tax amounts, can be found in page 115 and 116 of the appendix.

### 5.1.2 Actual contribution rates of households

Table 24 shows average contribution rates on a household basis. The average contribution rate is computed as follows:

Overall Tax $=$ Income Tax + CSG + CRDS - PPE - RSA - FA $--F C$

$$
\frac{\text { Overall Tax }}{\max \left(Y_{L}, Y_{L}-\text { Overall Tax }\right)}
$$

Where $Y_{L}$ is gross labor income.
This formula is equivalent to a simple tax/income ratio when the overall contribution rate is positive. When the contribution rates is negative, it measures the part of available income that comes from negative taxation (i.e. transfers). This has the advantage of making more sense for very small incomes, and of being properly defined (and equal to 100\%) when $Y_{L}=0$.

A more graphical illustration of average contribution rates ranked by fractile of households is provided in figure 10.

| fractile | $P_{f}$ | gross labor <br> income | income <br> tax |  <br> CRDS |  <br> RSA |  <br> FQ | Available <br> income | contribution <br> rate |
| ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: |
| All |  | $\mathbf{3 3 9 7 7}$ | $\mathbf{1 9 5 3}$ | $\mathbf{2 6 3 7}$ | $\mathbf{1 0 3 1}$ | 701 | $\mathbf{2 4 0 2 8}$ | $\mathbf{8 , 4 \%}$ |
| $0-10$ | 0 | 1157 | 0 | 90 | 4946 | 680 | 6432 | $-86,1 \%$ |
| $10-20$ | 5428 | 8736 | 0 | 678 | 2881 | 523 | 9578 | $-28,5 \%$ |
| $20-30$ | 11693 | 14007 | 5 | 1087 | 1585 | 511 | 11996 | $-7,2 \%$ |
| $30-40$ | 16069 | 17886 | 150 | 1388 | 942 | 478 | 13922 | $0,7 \%$ |
| $40-50$ | 19474 | 21216 | 360 | 1646 | 419 | 520 | 15587 | $5,0 \%$ |
| $50-60$ | 22984 | 25115 | 597 | 1949 | 172 | 560 | 17902 | $7,2 \%$ |
| $60-70$ | 27373 | 30330 | 919 | 2354 | 138 | 614 | 21291 | $8,3 \%$ |
| $70-80$ | 33639 | 38054 | 1362 | 2953 | 148 | 756 | 26497 | $9,0 \%$ |
| $80-90$ | 43002 | 50189 | 2249 | 3895 | 0 | 887 | 34245 | $10,5 \%$ |
| $90-95$ | 59090 | 66748 | 3882 | 5180 | 0 | 1010 | 44588 | $12,1 \%$ |
| $95-99$ | 76863 | 96078 | 8576 | 7456 | 0 | 1148 | 61319 | $15,5 \%$ |
| $99-99.9$ | 135141 | 179127 | 29418 | 13900 | 0 | 1553 | 104949 | $23,3 \%$ |
| $99.9+$ | 309114 | 527434 | 151023 | 40929 | 0 | 1705 | 266409 | $36,1 \%$ |

Table 24: Average contribution rates, all devices compounded, by household

Figure 10: Average contribution rates, all devices compounded, by household.

### 5.2 Assumptions about intra-household attribution of taxes and benefits:

In order to describe the features of the existing system at the individual level, we need to make assumptions as regards the way taxes and benefits are split within couples. We assume the following:

- Family Allocations and Family Quotient are split in two.
- CSG and CRDS are paid directly by the worker. We assume it is directly deducted from wage, and never enters intra household bargaining after that.
- As regards the other devices (PPE, RSA, Income Tax), there are two cases:
- if the tax rate resulting from compounding these three devices is positive, then the tax amount is split between spouses proportionally to their income level. He who earns an $\alpha$ proportion of household total labour income pays a proportion $\alpha$ of taxes.
- if the tax rate resulting from compounding these devices is negative (the household is beneficiary of the system), then benefits are simply split in two between
spouses.

In terms of marginal rates however, we make the hypothesis that for amounts that are split between spouses (that is all except CSG, CRDS, FA and FQ), each spouse faces the household's marginal tax rate. Otherwise stated, we assume that if a spouse makes the choice to modify her labor supply and hence her income, she has to compensate her partner for $100 \%$ of the tax variation caused by this decision.

In the following tables, we present PPE and RSA in an aggregated variable, "PPE\&RSA". This seems to make more sense, since RSA complements PPE benefits.

### 5.2.1 Reconstructed contribution rates of individuals

Table 25 shows average contributions rates on an individual basis, both for men and women. In this table, fractiles are first constructed without any gender distinction, so only men and women that belong to the same fractile of global population find themselves on the same line.

On the contrary, table 26 describes the contribution rates of women ranked by fractiles of women, and of men ranked by fractiles of men.

| Fractile | $P_{f}$ | gross labor income | income tax | CSG\& CRDS | PPE\&RSA | alloc | contribution rate |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Men\&Women |  |  |  |  |  |  |  |
| All |  | 25879 | 1573 | 1953 | 294 | 614 | 10,1\% |
| 0-20 | 0 | 950 | 11 | 69 | 857 | 771 | -62,0\% |
| 20-30 | 6173 | 9950 | 145 | 729 | 555 | 607 | -2,8\% |
| 30-40 | 13240 | 15850 | 306 | 1163 | 348 | 558 | 3,5\% |
| 40-50 | 18206 | 20083 | 445 | 1490 | 185 | 553 | 6,0\% |
| 50-60 | 21859 | 23698 | 614 | 1770 | 87 | 552 | 7,4\% |
| 60-70 | 25577 | 27709 | 887 | 2075 | 35 | 530 | 8,6\% |

### 5.3 Marginal retention and taxation rates

### 5.3.1 Methodology

The computation of marginal retention and taxation rates is done as follows: for each household, we suppose that yearly gross labor income increases by $100 €$. We convert this amount into taxable and net income. In order to do this, we use the marginal ratios described in section 4.1. Marginal ratios are the factor of the last term of the expression of average ratios described in table 7 .

For example, for a worker earning $1000 €$, an increase in $100 €$ in gross labor income (useful to compute CSG and CRDS) translates into an increase in $83,7 €$ in taxable income (useful to compute Income Tax and PPE), which itself translates to an increase in $78,8 €$ in net income (useful to compute RSA benefits). For a worker earning $10000 €$ a month, an additional $100 €$ in gross labor income means a $91 €$ increase in taxable income and a $89 €$ increase in net income.

We then sum up the excesses or deficits in available income produced by the effect this $100 €$ increase in income on all studied devices in order to obtain marginal tax rates. Marginal retention rates are simply the difference between 1 and marginal tax rates.

This process is straightforward for all devices except for PPE, because it is computed on individual income and not on household income. In the case of PPE for couples, we assume that the $100 €$ increase in gross labor income is equally distributed among spouses. Indeed, even if PPE is computed individually, it is paid as a tax reduction to the whole household, so there is reason to assume that PPE benefits are not treated differently, during the intra-household bargaining about the repartition of the tax burden among spouses, than other taxes or benefits. Hence, in the case of PPE, we stick to our beginning hypothesis: each spouse faces their household's marginal rate of taxation. This $50 / 50$ division in order to compute PPE implicit marginal tax rate is the measure that is relevant to labor supply decisions given this hypothesis on intra-household bargaining.

### 5.3.2 Actual marginal tax rates faced by households

| Fractile | $P_{f}$ | marginal income <br> tax rate | marginal CSG <br> rate | Marginal RSA <br> rate | overall marginal <br> rate |

Table 27: Marginal tax rates in the existing system, by fractiles of households

### 5.3.3 Translation into marginal rates faced by individuals

Applying the assumptions about intra-household bargaining described in section 5.2, we derive the following tables about marginal rates actually faced by individuals.

Table 28 shows marginal rates faced by individuals in the current system. We can see that in fractile 70-80 and above, marginal rates faced by women are higher than those faced by men. This is typically the effect of Income Tax on second earners. This is also visible in table 29, that computes fractiles separately for men and women: although women's fractiles have much lower boundaries than those of men, they still face comparable marginal tax rates. As illustrated in figure 11, we find a U-shaped curve of marginal tax rates, for households, for men and for women (the convexity being stronger for women). Of course, the devices causing marginal rates to be high are not the same at the top and at the bottom of the income distribution. As shown on this figure, the main "responsible" device for the high implicit marginal tax rates faced by low income households and individuals is RSA, whereas the device causing high marginal rates at the top of the income distribution is standard income

Figure 11: Marginal tax rates in the existing system, by fractiles of households
tax. The smallest marginal rates are faced by households located in the $80-95$ fractile. They are twice lower than those present at the extremities of the income distribution ( $20 \%$ vs 35-40\%).

Table 29: Marginal tax rates of the existing system, by same-gender fractiles

### 5.4 The effect of children

Children-related gains are central to the French system, and very important quantitatively. However, the way they should be implemented in an individual system does not seem obvious. Hence, our goal here is to describe the existing children-related gains of all devices (put together) as precisely as possible and to simulate a simple reform, in which the existing children-related gains are replaced by a yearly lump-sum transfer of $1780 €$ per child per family, to be split between spouses. A more refined treatment of this issue could constitute a central improvement of this work. However, it requires a normative reflection that goes beyond the scope of this dissertation.

### 5.4.1 Children-related gains : synthesis of the features of each device

Table 30 briefly summarizes the treatment of children in each of the existing devices. For more detail, see the previous section. Different logics that are put side by side: some devices yield children-related gains that are increasing in the level of income, some yield constant benefits, and some yield decreasing benefits with respect to income. Hence, it is worth seeing what happens when all devices are put together, and what shape children benefits actually have, as a function of income and number of children. As shown in figure 12, the dominant effect seems to be an increase of children-related benefit with respect to income. This is due to both an increase in the per-child gains with respect to income, and an increase in the average number of children with respect to income.

In the next two subsections, we propose two ways to measure the effect of children on taxes and benefits. The first way is to compute a contrafactual amount, for each device and for each household, that would be received by the household if it had no children. This gives an idea of distributional effects of existing children-related policies. The second way is to give one additional child to all couples that already have one, and see how they end-of the year income would be affected. This is more interesting in order to study incentives to have children provided by the existing system. One might want to keep them unchanged in individualization scenarios.

|  | per-child gain |  |
| :--- | ---: | ---: |
|  | income | total number of children |
| Income Tax | $\nearrow$ | $\nearrow$ |
| Family Allocations | no effect | $\nearrow$ |
| Family Complement | $\searrow$ | $\nearrow$ |
| RSA | $\searrow$ | no effect |
| CSG | no effect | no effect |

Table 30: Effect of income and number of children on the per-child gain brought by the different devices

These are the ceteris paribus effects; as we will show below, more ambiguous effects emerge when all devices are put together.

### 5.4.2 Average contribution rates with and without children

In this subsection, we study the difference between retention rates of every household and their contrafactual retention rate if they had no children. For those wanting to use the simulator, all these contrafactual variables are indicated by the suffix _SE. On average, having one child yields a tax or benefits advantage of $1780 €$ per year. However, there are strong differences in the per child gain of households, for two main reasons:

- income has an effect on children benefits
- the third and fourth child trigger stronger benefits or tax reductions that the first and the second one. Since the average number of children is higher at the top of the income distribution, this yields an even higher inequality.

Table 31 (illustrated by figure 12) shows this phenomenon. It shows that per-child gains in the current system are U-shaped, but globally increasing.

| fractiles of <br> households | $P_{f}$ | mean gross <br> income | number of <br> children | rsa w/o <br> children | rsa gain <br> with children |

Figure 12: Overall children benefits by fractile of households

### 5.4.3 Effect of an additional child on available income

In this section, we assume that all households with one child have an additional child. This gives insights about incentives to have additional children, but does not give a clear view of redistributive effects, because an additional child brings as much or more than the first one.

|  | Income Tax Gain | FA + FC | RSA Gain |
| ---: | ---: | ---: | ---: |
| ALL | $\mathbf{4 8 2}$ | $\mathbf{1 9 3 8}$ | -10 |
| $0-10$ | 0 | 1931 | 17 |
| $10-20$ | 0 | 1919 | -30 |
| $20-30$ | 0 | 1944 | -65 |
| $30-40$ | 1 | 1932 | -84 |
| $40-50$ | 31 | 1937 | -62 |
| $50-60$ | 104 | 1962 | 25 |
| $60-70$ | 226 | 1974 | 10 |
| $70-80$ | 344 | 2015 | 0 |
| $80-90$ | 579 | 2033 | 0 |
| $90-95$ | 953 | 1846 | 0 |
| $95-99$ | 1752 | 1787 | 0 |
| $99-99.9$ | 3634 | 1630 | 0 |
| $99.9+$ | 3755 | 1563 | 0 |

Table 32: Average fiscal and benefit gains from having one additional child among households that already have one child ( $10,1 \mathrm{Mn}$ households)

As expected, the fiscal gain from having one additional child is strongly increasing with revenue: It is less than $100 €$ for households below median income, and reaches more than $3500 €$ for the last centile. The reason it does not become higher is the ceiling described in section 4.2.2, which is at most $4600 €$ per child.

Family Allocation gains are flat over the distribution, but family complement gains are not (because of their conditioning on household income), which explains why the curve $\mathrm{FA}+\mathrm{FC}$ is decreasing with respect to income.

The effect of one additional child on RSA is ambiguous, but it is generally very weak when compared to the two others (it affects available income by at most $84 €$ in one fractile). The reason why this amount can be positive or negative is the variability in the number of children across deciles and its effect on the interaction between RSAn Family Allocations,

Figure 13: Average fiscal and benefit gains from having one additional child among households that already have one child ( $10,1 \mathrm{M}$ households)
and Housing Deduction (forfait logement): indeed, if the additional child is a second child, she will trigger eligibility to Family Allocations, that will be deducted from RSA (whose level will also increase, but less). For example, a second child triggers a $120 €$ monthly Family Allocations Benefits, and RSA is increased by $136 €$ but the housing deduction is also increased by $55 €$. The result is a $39 €$ loss in benefits.

Note that the effect of an additional child on RSA is much stronger for households that, even with this additional child, remain ineligible to FA and FC: for example, couple who have their first child. Then, no FA and FC is given to them, but their RSA guaranteed income is raised by $136 €$.

### 5.4.4 Redistributive effects of a lump-sum children benefits reform

As can be seen above, the question of how children should be treated is complex. Childrenrelated gains can not be left as they currently are it is in any individualization scenario, but there are many possibilities as regards how it should be replaced.

In our scenarios below, we replace the existing children-related fractures of all devices by

| fractile | $P_{f}$ | gross labor income | current children benefits | flat-rate benefits | households |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  |  |  |  | winners | losers |
| All |  | 29994 | 899 | 899 | 89\% | 11\% |
| 0-10 | 0 | 1442 | 1027 | 850 | 82\% | 18\% |
| 10-20 | 5428 | 8866 | 604 | 509 | 89\% | 11\% |

Table 33: Redistributive effects of a flat-rate reform of children benefits (including all indirect benefits given to families with children through income tax and rsa)

As can be seen, such a reform would make few losers, but very concentrated at the top of income distribution. For the number of households in each fractile, see the previous table.
a lump-sum transfer that only depends on the number of children, and no longer of the level of income. We simply give an amount of $1780 €$ per year and per child to every household, and split in two in the case of couples. This amount is chosen because it is the average perchild gain in the current system, which makes the reform neutral from the point of view of budget balance. The distributional effects of such a reform are described in table 33. This amount is split in two in the case of a couple.

## 6 Individualization scenarios

### 6.1 Properties and constraints of simulated reforms

In the following section, we experiment a few experimental scenarios of fundamental reform of the system.

While leaving social security contributions unchanged, we simulate various possible new systems replacing Income Tax, CSG, CRDS, PPE, RSA, and Family Benefits. This subsection describes the properties these systems should yield.

All devices are merged into one simple, easy to understand schedule, which yields efficiency gains and maintains roughly comparable tax revenues. The schedule is expressed as a function of gross labor income, which removes the complicated distinctions between gross income, taxable income and net income. These differences have been taken into account in the simulation of the current system, but they are directly included in the design of our experimental tax schedules, and hence no longer appear.

In order for the new system to be easily understandable, it is expressed in an average rate schedule (as opposed to the marginal rate schedule existing in today's income tax, for example). The main advantage of expressing our schedule in terms of average tax rates is increased legibility: with one look at the table, a taxpayer can see that with her income $G$, she will be subject to a tax rate $f(G)$, without needing to make any further computation. The downside is that marginal tax rates become implicit, and tend to be more erratic than in marginal-rate schedules. Still, we believe that this increased legibility alone could be the source of efficiency gains.

The system also has to be roughly comparable to today's system in terms of global tax revenue. However, the practice of income splitting (couple income splitting as well as family income splitting) is suppressed, and taxes are paid on an individual basis. The treatment of children is also strongly simplified: every family receives a lump-sum transfer of $1790 €$ per child and per year. This amount corresponds to the average gain brought by one kid in the current system. The transfer is split equally between parents. Redistributive effects of such a measure have been studied in section 5.4 ,

Individual taxation is at the core of the possibility of having efficiency gains, but it comes at a high price if implemented to its full extent: indeed, full individualization means, for example, giving benefits to non working people who have a relatively rich spouse. This illustrates two potentially very strong negative effects:

First, in terms of budget balance, it triggers a dramatic increase in benefit (negative tax) spending;

Second, in terms of efficiency losses, giving out benefits to people who have a relatively rich spouse will in most cases lead to increasing their implicit marginal tax rate ${ }^{26}$,

Hence, we also simulate semi-individual systems, where individual treatment is implemented when the tax rate is positive, and familial treatment is kept when the tax rate is negative. Defining a limit and a correct transition between these two systems (individual at the top, familial at the bottom) raises numerous questions, which are dealt with in section 6.5

With these criteria and properties in mind, we experiment three possible reforms. They differ by their schedule table, and by the level of individualization they implement. Schedule 1-i has a schedule that reproduces average tax rates faced by singles in the current system, and is implemented in a fully individual way. Schedule $2-i$ reproduces the average tax rates faced by couples, and is also implemented in a fully individual way. Schedule $3-i$ is an experimental scheme that reproduces the average tax rates faced by couples for most of the income distribution, but yields much higher tax rates for very high income levels (up to 70\% at $1200000 €$ a year). Finally, Schedule $3-f$ is like schedule $3-\mathrm{i}$, but is implemented in a semi-

[^15]individual way, that is with familial treatment at the bottom of the income distribution. In schedule names, $i$ means fully individual, and $f$ means semi-individual (familial treatment at the bottom of income distribution). We also provide a description of the results of semiindividual versions of reforms 1 and 2. They are availaibe upon request.

For each reform, we also simulate a basic response to changes in marginal tax rates. We differentiate between elasticities of men and women. And among men and women, we make another distinction between intensive elasticities at the top (small responses to small variations in marginal tax rates, e.g. a one-hour increase in weekly work time) of the income distribution, and extensive elasticities at the bottom (stronger responses to higher variations in marginal tax rates, like the decision to start working, or to switch from a part-time job to a full-time job).

The issue of elasticities raises the following questions: what are reasonable elasticities to use, for men and women? What kind of elasticity, from intensive and extensive, should be taken into account, depending on the level on income? What elasticity levels must we suppose in order to make the reform fully feasible, or in order to compensate as many losers as possible?

The next section briefly describes the elasticities used, before going into individualization scenarios.

We believe that the third scenario is the most interesting one: the reader with little time is advised to begin with section 6.5 page 91 .

### 6.2 Labor Supply Elasticities and Responses to reforms

In order to evaluate the efficiency gains brought by our reform scenarios, we need to compute the labor supply response as a function of the variation of marginal tax rate induced by our reform simulations, and the intensive and extensive labor supply elasticities.

### 6.2.1 Intensive Elasticities

Intensive elasticities are the general case: they describe the response of individuals to a small variation in their tax rates. This is the likely case for people who are already working, and
who might decide to increase or reduce their work time by a few hours.
We call $\zeta_{s}^{i}$ the individual's intensive labor supply elasticity, with $s=M$ for men and $s=W$ for women. Let $\tau_{0}$ be the previous tax rate of the individual, and $\tau_{1}$ be the new marginal tax rate, resulting of the reform. We call $G$ the gross income, which we identify with labor supply.

Then, by definition of labor supply elasticities, we have:

$$
\zeta_{s}^{i}=\frac{\frac{\partial G}{G}}{\frac{\partial(1-\tau)}{1-\tau}}
$$

Which leads us to:

$$
\Delta G \simeq \zeta_{s}^{i} \cdot \frac{\tau_{0}-\tau_{1}}{1-\tau_{0}} \cdot G
$$

For now, we set

$$
\begin{gathered}
\zeta_{\text {men }}^{i}=0 \quad \text { and } \\
\zeta_{\text {women }}^{i}=\frac{1}{2}
\end{gathered}
$$

### 6.2.2 Extensive Elasticities

In our simulations, we apply extensive elasticities only to people with 0 labor income. We model their labor market entry decision as follows: we suppose an extensive labor supply elasticity of $\zeta_{s}^{e}$, which, following the results of Piketty (1998), we calibrate to $98 \%$ for women. We leave them to $0 \%$ for men.

We model labor market entry as taking a minimum wage full time job, meaning an annual gross labor income of $15852 €$. Then we suppose that every zero-labor-income person has a probability $P$ to enter the labor market, depending on her extensive labor supply elasticity and the variation in marginal tax rates in the following way:

$$
P=\zeta_{s}^{e} \cdot \frac{\tau_{0}-\tau_{1}}{1-\tau_{0}}
$$

For example, if $\zeta_{s}^{e}=1$, a person whose labor income is 0 and who used to face a $50 \%$ marginal tax rate under the old system and now faces a $40 \%$ marginal tax rate has a $1 \cdot 10 / 50=20 \%$ probability to enter the labour market and earn $15852 €$ a year.

### 6.3 First Scenario

### 6.3.1 The schedule

This table aims at reproducing contribution rates faced by singles with no children in the simplest case. Children are treated with the lump-sum reform described above.

| gross income | average tax rate |
| ---: | ---: |
| 0 | 0 |
| 12766 | $0,0 \%$ |
| 13565 | $1,5 \%$ |
| 15170 | $1,6 \%$ |
| 21640 | $11,9 \%$ |
| 35830 | $14,4 \%$ |
| 95559 | $24,2 \%$ |
| 181357 | $31,9 \%$ |
| 1000000 |  |
| and above | $40,0 \%$ |

### 6.3.2 Description of measures presented

The following tables, that describe the effects of the reform at the household and at the individual level contain the following information:
current total tax gives an idea of the amount levied by the current system. It is decomposed in two variables: current tax revenue, that describes the aggregate amount of positive tax collected for each fractile, and current spendings, that describes the amount spent on negative taxes (benefits). Same goes for new total taxes, new tax revenue and new spendings.

These variables only measure the effects of the change in schedules, and do not yet take into account variations in labor supply.

Fiscal gain estimates the variation of collected tax amount due to labor supply response, which is the amount by which individuals increase their labor supply in response to the variation in marginal tax rate they face, according to their labor supply elasticity.

Households better off and bouseholds worse off show, for each fractile, the proportion of households that find themselves better off or worse off in terms of taxes paid or benefits received after the reform. These variables focus on the change of schedule, and do not include the effects of variations in labor supply responses.

Note that given our calibrations about labor supply elasticities, only women react to changes in marginal tax rates, which makes the results easier to read.

Variables better off (with response) and worse off (with response) do that: they include the effect of the reform on labor supply (and hence on household income) and the variation in taxes triggered by this effect in the comparison of before and after reform situation.

Variables increased marginal rates and decreased marginal rates measure the proportion of households in which at least one member faces an increase (resp decrease) in marginal tax rates after the reform. This means that in tables that compare households, the sum of these two variables is not necessarily $100 \%$. In tables studying individuals, they are simply the proportion of individuals whose marginal increase (resp decrease), and their sum is $100 \%$.

Finally, new marginal tax rate and current marginal tax rate compare new and current marginal tax rates. It should be noted that average and fractile-average marginal tax rates include a weighing of rates by income, as described in section $H$ of the appendix $\sqrt{27}$. This gives the illusion that our reforms yield strong increases in marginal tax rates, when it is not always the case: indeed, with this computation, marginal tax rates of high-income individuals have a strong influence on the average, when marginal tax rates of zero income individuals(who should benefit from the reform) have none. This is the same for each fractile: the top of the fractile weighs more than the bottom.

The general increase in marginal rates comes from the children-related reform: children

[^16]used to reduce their household marginal income tax rates, which is no longer the case, since a lump-sum benefit is neutral on marginal tax rates. As we show in section 6.8, and in section $G$ of the appendix, labor supply response is proportionally higher if we focus on people with no children.

Table 37: 1-i:Labor supply responses of married women, ranked by their husband's income

These tables are not commented one by one, but compared across the three scenarios and their variants in section 6.8.
6.4 Second Scenario

### 6.4 Second Scenario

### 6.4.1 The schedule

| gross income | average tax rate |
| ---: | ---: |
| 0 | $0,0 \%$ |
| 18280 | $0,0 \%$ |
| 19204 | $1,5 \%$ |
| 23137 | $1,6 \%$ |
| 31001 | $3,2 \%$ |
| 44715 | $12,1 \%$ |
| 71663 | $30,0 \%$ |
| 190440 | $24,2 \%$ |
| 2100000 |  |
| and above | $40,0 \%$ |

This schedule aims at reproducing the average tax rates faced by couples. This schedule has many flaws and side effects, which are presented in section 6.8.

The effects are described with the same set of tables than for the previous scenario. A guide to reading these tables is available in section 6.3 .2 page 77 .

### 6.4.2 Redistributive and marginal tax rate effects: households

| fractile | gross income | current total taxes | new total taxes | new tax revenue | new spendings | current tax revenue | current spendings | fiscal gain | labour supply response |

Table 41: 2-i:Labor supply responses of married women, ranked by their husband's income

We now turn to the third scenario, which we implement in a more refined way: fully individually (as in previous scenarios), semi-individually, and, in the appendix, fully and semi individually but on households with no children only, in order to set aside the issue of the treatment of children.

### 6.5 Third Scenario: schedule

From now on, we would like to experiment the following schedule (presented in table 42 below). As regards the bottom of the income distribution, we stick to our objective of the previous sections, which is to create a schedule that remains close to the exiting schedule faced by couples without children.

However, we depart from this goal as regards the rates applied to the top of the distribution: we set the average tax rate of very high incomes to $70 \%$. Figure 14 illustrates this new schedule, and figure 15 compares this schedule to average rates currently faced by couples without children.

Figure 15 (top) focuses on the bottom of the income distribution, while 15 (bottom) gives a broader view, which shows the very strong increase in tax rates for high incomes induces by this schedule.

In these comparisons, we mean by "couple without children" working couples over 25, whose only source of income is salary, and who do not have any special tax reduction (like disability reductions).

| Gross labor | mean tax |
| ---: | ---: |
| income | rate |
| 0 | 0 |
| 12000 | $0,00 \%$ |
| 24000 | $10,00 \%$ |
| 60000 | $20,00 \%$ |
| 120000 | $30,00 \%$ |
| 360000 | $50,00 \%$ |
| 1200000 | $70,00 \%$ |
| 1500000 | $70,00 \%$ |

Table 42: Tax schedule simulated in section 6.5

### 6.6 Third schedule with fully individual implementation

We now compare the effects of this new hypothetical schedule when applied to the actual population of taxpayers. We study the two alternatives presented in the introduction of

Figure 14: Experimental tax schedule number 3
this section: a fully individual implementation, and a semi-individual implementation. We study the redistributive effects of the reform, as well as the effects on marginal rates faced by individuals and expected elastic responses of labor supply.

We study all households whose head is over 25 and below 65. However, since the lumpsum children benefit reform has strong effects on redistribution effects as well as on marginal tax rates, we also provide tables computed only on households without children. These tables are in the appendix.

### 6.6.1 Redistributive and marginal tax rate effects: households

A guide to reading these tables is available in section 6.3.2 page 77 .
Table 43 shows the redistributive impacts of full individual implementation of the above schedule on a household basis: as an be seen here, labor supply response is small (less than $0,5 \%$ ), and the overall cost of the reforms in terms of overall benefit spendings is very large. Positive effects on labor supply are very concentrated on the $60-70$ fractile.

Figure 15: Comparison of the third schedule and tax rates currently faced by couples without children

The upper figure focuses on incomes below $150000 €$ while the second one gives a broader view of tax rates on very high incomes.

| fractile | gross income | current <br> total taxes | new total taxes | new tax revenue | new spendings | current <br> tax <br> revenue | current spendings | fiscal gain | labour supply response |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

Table 46: Labor supply responses of married women, ranked by their husband's income, in the fully individual system

### 6.7 Third scenario with semi-individual implementation

We now turn to a semi-individual implementation, which leaves household-based tax treatment at the bottom of the distribution. Specifically, when one household member is eligible to a negative tax rate, we then treat the household as a whole as one single individual, with no concept of income splitting. This treatment concerns about $40 \%$ of married couples. Other transition mechanisms could be thought of, in order to reduce this amount. The effects of this mechanism are discussed in section 6.8.

Table 50: Labor supply responses of married women, ranked by their husband's income, in the semi-individual system

### 6.8 Comparison of the three scenarios

The first schedule, in which we implement a system that reproduces current contribution rates of singles without children, and treat all individuals separately, yields significant labor supply gains ( $+1,25 \%$ ), but is quite demanding in terms of budget balance: spendings increase from 23Bn to 30Bn, and the fiscal gain triggered by labor supply responses is not close to compensating for it.

The second schedule, in which we reproduce contribution rates for couples seems to have all the disadvantages of the first one, and not its advantages: spendings skyrocket to $60 \mathrm{Bn} €$ (this is because we also give to individuals what couples earn in RSA in the current
system), and labor supply response is weaker. Hence, this scenario can be discarded.
All scenarios seem to make poorer households better off and richer households worse off, since richer households benefit more from income splitting. The redistributive effects measures computed on individuals (ant not on households) are much more erratic, but this is linked to our hypotheses on intra-household bargaining. This is not too much of an issue since the measure that matters the most to the political acceptability of such reforms is probably the one made on households.

None of our reforms are completely neutral from the point of view of across-households redistribution, which can make them less acceptable. It should be a direction for future research to try to maintain the efficiency gains we identify here while finding a way to reduce unwanted across-household redistribution. Surely, dealing with the issue of childrenrelated benefits, and finding a better system than pure lump-sum per-child transfer could allow to achieve that.

As regards labor supply responses, they seem concentrated at the upper middle and the top of the income distribution (looking at wive's labor supply response as a function of their husband's income) in all the scenarios. This is where the income-splitting effect of income tax is the strongest, and corresponds to our expected gains of individualization. There is also a strong labor supply response in decile 20-30 of men's income: this corresponds to our hypothesis on extensive elasticities, that makes a significant number of women jump from zero income to minimum wage. These results are confirmed by a comparison with the simulation on households with no children in section $G$ of the appendix.

One might be concerned with the effect of the $70 \%$ rate on high incomes of the third schedule. It is, in fact, reasonable: since most people that face such tax rates are men, the overall labour supply response of individuals that faces more than $40 \%$ tax rates in the new system is less than $0,53 \mathrm{Bn}$, which is very low when compared to the effect of women entering the labour market through the mechanism of extensive elasticities: in setting 3 $f$ (semi-individual implementation), more than 192000 women enter the labour market, causing efficiency gains of $3,05 \mathrm{Bn}$.

The third scenario seems more interesting than the others, especially when comparing its fully individual version to its semi-individual version. The fully individual version yields
a weak labor supply response (less than half a percent), and very high spendings (40Bn). However, the semi-individual setting is more promising.

In this semi-individual setting, about $85 \%$ of households are treated with the fully individual schedules, and $15 \%$ remain under a household-based system. If we focus on married couples, about $60 \%$ of them are treated in a fully individual way. $6 \%$ of them still receive benefits as a household, and $34 \%$ of them were denied benefits because of the income of one spouse.

The effects of such an implementation seem encouraging: spendings are maintained at reasonable levels, and the labor supply response is the biggest of all scenarios, $+1,4 \%$. With a Cobb-Douglas $1-\alpha$ coefficient of $\frac{2}{3}$, this roughly yields a $0,9 \%$ increase in GDP. However, redistributive effects are strong: $90 \%$ of household at the bottom of income distribution are better off, and $0 \%$ at the very top (last $0,1 \%$ ).

Finally, the efficiency gains are much stronger if we focus on households without children only. In this case (tables available upon request), they reach $+3 \%$, raising potential GDP gains to $2 \%$. This emphasizes the need for future research as regards the ideal treatment of children.

## 7 Conclusion

This dissertation aims at being a methodological contribution that eases the way for future research.

Most of the work has been dedicated to building the simulator and describing the existing system and its features. However, the existing system is currently evolving: the last major reform, the implementation of RSA, only took place a few weeks before this dissertation was written. It might be worth seeing what experience can reveal about these reforms, which we will not be able to know before a few years, or at least a few months.

We hope that the simulator and its presentation could be useful to non-French speaking people who wanted to discover the French system, and that our presentation of its aggregated features in terms of average and marginal contribution rates could provide a clear overall sight to people who are actually part of the system as taxpayers or benefit receivers, and might have been confused by its complexity or its fragmented nature.

The third goal of this work, which is the use of the simulator in order to determine ideal reforms, supposes a broad normative reflexion that goes beyond the scope of this dissertation. Again, it should be stressed that the individualization scenarios are at an experimental state; we apologize for the somewhat raw way their are presented. We hope that this contribution will be of some use to this future research and debates, and that the findings presented here about the efficiency effects of individualization can constitute a first clue towards actual reforms in the future.

## A Appendix

## A. 1 Summary statistics on our data

| fractile | $P_{f}$ | average income <br> of the fractile | wages | replacement | pensions | non wage <br> earners | capital <br> income |

Table 52: Proportion of households who have each type of income. (ERFS variables)
Example : $82 \%$ of households of the last centile have non zero capital income; $66 \%$ of all households have non zero wages. These are ERFS data before re-weighing.

## B The program: presentation

The program is available upon request. It is approximately 7000 lines of SAS program, which corresponds to 200 pages. It comes with a small documentation. Here is the general structure:
(We only present programs that make the simulation. Programs that provide statistics are not included in the description belowe).
income.sas consolidates various measures from income using the fields of tax declarations. It also makes the conversion between net, taxable and gross labour income
simple cases.sas creates a simple table of households with "good properties" (no children, no special situations, no retirees, ...), and can be useful to simulate reforms on simple polar cases only. It is to be used instead of income. sas.
income tax.sas computes net taxable income, and income tax (quotient familial, plafonnement du quotient familial, décote), as well as marginal income tax rates and contrafactual income tax rates in the case of simple income tax individualization. It also computes family benefits, like Family Allocations and Family Quotient
ppe. sas computes PPE, PPE marginal rates and contrafactual PPE amounts.
RSA. sas computes RSA, and compounds all features of the system in terms of marginal and average implicit tax rates.
scenarios.sas simulates our new average tax rates schedules. For each schedules, it simulates both the fully individual implementation and the semi-individual implementation.

These programs need to be used in this precise order for the simulator to work.
There are other programs in the simulator, that study the effect of children, marriage penalty, or that extract official aggregates from impots.gouv PDF files. These can be used in any order.

## C Methodological notes about the data

## C. 1 Computing income aggregates

In ERFS, names of variables are very close to the code names of standard tax declaration sheet fields. They are coded on 4 characters, of the form $\_n \mathrm{XX}$.

- _ is invariable, and is always
- $n$ is the number of the section on which the field is positioned on the tax declaration sheet
- XX is the codename of the field, written next to it.

For example, the variable "your salaries" is _1AJ, and the variable "your partner's salaries" is _1BJ. Note that the two first characters can be dropped, since the combination XX already uniquely identifies every field.

Then, the way of aggregating these fields in order to obtain income aggregates is precisely described in the official section I.2, below. This document is in French. Non-French speakers can read the SAS program income.sas (available on the website), which does the same in a self-explanatory way.

## C. 2 Household head, spouses, first and second earners in the data

Methodological note about French income tax data: in the case of a couple, the head of the household (personne de référence) files the tax declaration, and reports his partner's (conjoint) incomes. It should be stressed that personne de référence and conjoint are not synonyms for first earner and second earner: indeed, the head of the household (personne de référence) is necessarily the man, even if he earns less money than his partner. In rare cases, the first earner is neither the household head nor his partner, but a dependent. This means that the identification of first and second earners need to be done carefully, on a per-household basis.

Incidentally, this tradition of making the man the head of the household raises a problem identifying the gender of some individuals in the data: indeed, they were not designed to include same-sex couples, so only the gender of the household head is available; the conjoint
being always supposed to be a woman. ERFS data allow to overcome this problem, since they also contain precise information about individuals; but tax declaration data alone do not.

## D Computing income tax, CSG, PPE, RSA

As regards income tax and CSG, there computation is already precisely described in the related sections. However, we felt the need to go over a few additional technicalities about PPE and RSA.

## D. 1 PPE: computing the coefficient of conversion

In section 1 of the tax declaration, every taxpayer has to fill additional information that allows the administration to compute her PPE benefits. The role of this coefficient is described in the body text, in section 4.3. This coefficient can not be found in the data. Hence, we here suggest a way to compute it. This computation can be useful in order to simulate, for instance, responses to variations in marginal tax rates : incomes increase, but in order to be precise, time-coefficients should be adapted too.

First, there is a dummy describing whether the individual is working full-time or not. This variable is _1AX for the head of the household, and _1BX for his partner. In couples, the head of the household is always the man. If this variable is set to 1 , then the coefficient should be too.

Then, there are two measures of an individual's time quote : the number of hours worked within a year (_1AV for the household head, _1BV for the other), and the number of days worked (_1NV and _10V). In principle, salary-earning workers should fill in their number of hours worked, and non salary-earning workers their number of days. There can be combinations, since people can have various occupations over one year.

Here, it should be noted that there can be mistakes with the data, so it is safer to add boundaries to the computation of the coefficient.

Hence, we compute the coefficient as follows, for each individual of the household (if
their "full time" variable is negative only):

$$
C=\max \left(0, \min \left(1, \frac{\text { Hours worked }}{1800}+\frac{\text { Days worked }}{235}\right)\right)
$$

Note that there might still be " 0 " values. In that case, we change them to 1 . (if these observations have no labor income attached, they will still not receive any PPE anyway; If they do, then it will be computed on the full-time equivalent formula).

Then, this coefficient can be used as described in section 4.3.2.
Note that when simulating a response in labor supply, this coefficient should be adapted, except when one has reason to believe that the response will be an augmentation in productivity and not in time worked. This is easily done, since the data contain the wage and non-wage income as well as the number of hours worked. This allows to compute an approximation of hourly salary, which allows in turn to know the number of additional hours worked and hence the variation in the coefficient. We replace aberrant values by the gross minimum wage rate, which was an hourly $8,71 €$ in 2008.

## D. 2 RSA deductions and the presence of capital income

In order to accurately simulate RSA benefits, it is necessary to gather as much data as possible about the household's other sources of income. This is very important because of the of RSA, meant only to complement existing sources of income. Given the complexity of the social security system, there can be many. ERFS data allow us to do just that, since they contain information directly retrieved from government organs distributing such benefits. However, if one wants to stick to tax data (for instance, the tax files contained in ERFS data), one needs to compute revenue to be deducted. Apart from Family allocations and specific social benefits, capital income should be deducted from RSA benefits at a $100 \%$ rate. In order to compute capital income from the tax declarations, one needs to compute land revenues (revenus fonciers), by adding fields in section 4 of tax declaration sheets, to capital gains (plus-valuessection 3), and to asset revenues (Revenus des capitaux mobiliers, section 2). However, because of many exemptions, not all capital income appears in income tax data. As explained in section 2, we observe roughly $40 \%$ of total capital income. For simplicity,
we multiplied everyone's capital income by 2.54 (ratio between capital income reported by the French government (Conseil des prélèvements obligatoires) and capital income observed in the data). This might be a source of biases, so it is probably safer to use ERFS data on capital income (not in tax declarations) rather.
D. 2 RSA deductions and the presence of capital income 113

## E Income tax individualization within the existing schedule

| fractile | AVERAGE RATES |  |  |  | TF | MARGINAL RATES |  |  |

* in "without children" tax rates. Everything is expressed as a function of gross* (but net of social security contributions) income, as opposed to the rest of this paper.

This table reflects an experimental implementation of separate filing while keeping the existing income tax unchanged. However, we increase tax bracket's boundaries by $13 \%$ in order to maintain overall tax revenues unchanged, and we sreplace the existing child benefits (due to family income splitting) by a lump-sum tranfer of $610 €$ per child.

We can see that if we consider people without children, this experimental system could strongly reduce marginal tax rates, especially for women

## F Additional tables and figures describing the current system

Figure 16: [Singles]Implicit and explicit tax rates as a function of gross labor income.
These curves are computed for single people (men or women), with no children, and whose income is $100 \%$ salary. For PPE computation, these people are assumed to work full time.

## G Simulation of our third scenario: no children

We here simulate the third schedule in its two possible implementations, but focusing only on couples without children. This sheds light on the actual features of individualization, without the strong effects of the children-related reform.

Figure 17: [Couples]Implicit and explicit tax rates as a function of gross labor income.
These curves are computed for couples with no children, and whose income is $100 \%$ salary. For PPE computation, these people are assumed to work full time.

Table 60: No children: Labor supply responses of married women, ranked by their husband's income, in the semi-individual system

## H The concept of average marginal rate

In order to compute an average marginal rate $(\bar{M} R)$, for all individuals or households as well as within each fractile, we first compute everyone's individual marginal tax rate:

$$
\frac{\partial T(Y)}{\partial Y} \simeq \frac{T(Y+100)-T(Y)}{100}
$$

Then, we weight every individual (or household) marginal tax rate by its labor income:

$$
\bar{M} R=\sum_{i \in I} P_{i} Y_{i} \cdot \frac{\partial T(Y)}{\partial Y}
$$

for any subset $I$ of the individuals in the panel. In our study, $I$ is most of the time the whole population or fractiles, computed on various concepts of income. In ERFS 06 data, $P_{i}$ is the variable WPRM.

This weighing makes sense because it makes us able to easily find the amount of tax actually levied by the state for any infinitesimal variation of everyone's income.

## I Official income tax documentation

## I. 1 Examples of tax files

- Tax form 2042: this is the most common tax file. Every taxpayer has to file it. It addresses the most common sources of income. This form available on http: //www.impots.gouv.fr, or upon request. The number inside each field represents the aggregate amount of income declared in the field in 2006. This is an official document of the French tax administration, also available on the website http://www. impots.gouv.fr.
- Tax form 2042c: this form can be added to the 2042 form, and addresses more complex cases, like income sources of farmers, very small businesses or non wage-earning workers.

## I. 2 Notices

2009 income tax notice: these sheets are sent to every taxpayer along with the income tax file to complete. They contain all information one needs to directly compute her income tax. They can also be downloaded from http://www.impots.gouv.fr. We do not provide direct links to these documents here, since their URLs are subject to change.

## J Example of 2042 Tax form, filled with the 2006 aggregates

- Si vous déposez une déclaration pour la première fois, cochez la case
Sinon, indiquez votre $n^{\circ} \mathrm{FIP}$ $\qquad$
$\square$
et votre $n^{\circ}$ fiscal
le $n^{\circ}$ fiscal de votre conjoint $\qquad$
Vous trouverez ces numéros sur votre déclaration de revenus ou votre avis d'imposition de l'année dernière. Leur indication facilitera le rapprochement des acomptes ou mensualités que vous avez déjà payés et de l'impôt dû.
- Pour les couples mariés: Madame, si vous souhaitez voir figurer votre nom de naissance sur nos courriers, veuillez cocher la case : $\square$
* ou partenaire du Pacs

## Redevance audiovisuelle

Cochez la case, si aucune de vos résidences (principale ou secondaire) n'est équipée d'un téléviseur (voir notice). $\quad \varnothing R A$

## CHANGEMENTS D'ADRESSE

En cas de changement d'adresse en 2006 ou en 2007, merci de compléter les informations ci-dessous :
Si vous avez déménagé en 2006, indiquez votre adresse au 1 er janvier 2006

Si vous avez déménagé après le 1 er janvier 2007, indiquez votre adresse actuelle (pour recevoir sans difficulté votre courrier)

| $N^{\circ}$ et Rue |  | Bâtiment |
| :--- | :--- | :--- |
| Code postal | Commune | Appt. |

## SIGNATURE DU OU DES DÉCLARANTS

À le 2007

Votre $n^{\circ}$ de téléphone
Votre adresse internet

## N'oubliez pas de remplir le cadre A

- Si vous élevez seul(e) votre ou vos enfants : complétez le cadre B;
- Si vous avez des personnes à charge (autres que les enfants rattachés) : complétez le cadre C;
- Si un ou plusieurs de vos enfants majeurs ou mariés demandent leur rattachement : complétez le cadre D.

## A i Situation du foyer fiscal en 2006

| Mariés | Célibataire $\quad$. $\quad$ Divorce/séparation |  |
| :--- | :--- | :--- |
| Veuvage | Pacs |  |

En cas de changement en 2006

Vous devez souscrire une déclaration pour chacune des périodes avant et après votre changement de situation de famille (voir notice).

## Situations particulières

Situation des enfants en cas de célibat, divorce, séparation ou veuvage Vous vivez seul(e) et vous avez eu un enfant décédé après l'âge de 16 ans ou par suite de faits de guerre (Complétez aussi la ligne H).
Vous vivez seul(e) et vos enfants (majeurs ou mariés ; mineurs imposés en leur nom propre) ne sont pas comptés à votre charge ou n'ont pas demandé leur rattachement à votre foyer (Complétez aussi la ligne H).

Année de naissance de votre enfant dernier-né, ouvrant droit à I'attribution d'une demi-part supplémentaire.
Vous ne vivez pas seul(e)
Un au moins de vos enfants à charge ou rattaché est issu du mariage avec votre conjoint* décédé.

## Situations donnant droit à une demi-part supplémentaire

Titulaire d'une pension (militaire, accident du travail) pour une invalidité d'au moins $40 \%$ ou d'une carte d'invalidité d'au moins $80 \%$ (joignez une copie de la carte) :

Vous remplissez ces conditions.
Votre conjoint* remplit ces conditions, ou votre conjoint*, décédé en 2006, remplissait ces conditions.
Titulaire de la carte du combattant ou d'une pension militaire d'invalidité ou de victime de guerre :

Vous êtes célibataire, divorcé, séparé, veuf**et :

- vous avez plus de 75 ans et remplissez ces conditions:
- vous avez plus de 75 ans et votre conjoint*, décédé, remplissait ces conditions:
- votre conjoint*, âgé de plus de 75 ans, décédé en 2006, remplissait ces conditions.

Vous êtes mariés ou liés par un PACS et l'un des deux déclarants, âgé de plus de 75 ans, remplit ces conditions.

Vous avez une pension de veuve de guerre.

## B I Parent isolé

Vous êtes célibataire, divorcé(e), séparé(e), veuf(ve)** et vous vivez seul(e) avec votre (ou vos) enfant(s) ou des personnes invalides recueillies sous votre toit ; pour bénéficier de la majoration du nombre de parts et éventuellement de la majoration de la prime pour l'emploi, cochez la case:
T

## C i Personnes À Charge en 2006 (voir notice)

Précisez ci-dessous TOUTES LES PERSONNES À VOTRE CHARGE autres que les enfants qui demandent leur rattachement, en indiquant pour chacune son année de naissance. (Ne comptez pas les enfants qui souscrivent une déclaration séparée ou qui sont déclarés à charge par une autre personne). Indiquez leurs nom et prénom ci-dessous. Si vous n'avez plus de personne à charge, portez « 0 » dans la ou les cases F à R .
Indiquez les enfants en résidence alternée sur la déclaration n 2042 C. Enfant(s) non marié(s) de moins de 18 ans au 01-01-2006 ou né(s) en 2006 ou handicapé(s) quel que soit l'âge : Nombre: F 15990579
Année de naissance :
 Année de naissance :

Personne(s) vivant sous votre toit et titulaire(s) de la carte d'invalidité d'au moins $80 \%$ :
Nombre : R
32877
Année de naissance

Précisez ci-dessous les noms et prénoms de vos enfants ou autres personnes à charge

## D I Rattachement d'enfants majeurs ou mariés en 2006

Nombre d'enfant(s) célibataire(s) (ou veufs ou divorcés) majeurs sans enfant: J 1891215 Nombre d'enfants mariés ou non mariés chargés de famille :

N 953
(y compris le conjoint et les enfants)

## ET LA TÉLÉDÉCLARATION ?

## Désormais, vous pouvez télédéclarer en cas de changement de situation de famille sur www.impots.gouv.fr

- si vous vous êtes marié, «pacsé» ou si vous avez divorcé en 2006 ;
- si vous êtes âgé de plus de 22 ans et si vous étiez rattaché l'année dernière à la déclaration de revenus de vos parents.

[^0]:    ${ }^{1}$ Tax reductions triggered by marriage strongly reduces the number of cases where people could refuse to get married because of taxation. There is almost always an intra-household bargain in which marriage (and joint filing) makes both partners better off.
    ${ }^{2}$ these devices are described in section 4

[^1]:    ${ }^{3}$ For a thorough explanation about ERFS methodology, see www.insee.fr
    ${ }^{4}$ See the sheet reproduced at the end of this dissertation, page 132

[^2]:    ${ }^{5}$ This computation is quite precise for lower incomes, but a bit off for higher incomes, since minimum wage is increased by inflation plus half the gain in purchasing power of the average income. This seems like an acceptable approximation, since it little affects marginal tax or implicit tax rates facesby taxpayers, which are the most important parameters in order to evaluate efficiency gains linked to individualization.
    ${ }^{6}$ This lower limit can seem a bit arbitrary, but it is the lower limit of eligibility to many social benefits schemes, like guaranteed minimum income or RSA, that are part of our simulation. This is why we restrict the analysis to people above 25 .

[^3]:    ${ }^{7}$ We define labor-related income as the sum labor income (a concept that, in this paper, already includes replacement income), and pensions and rents.

[^4]:    ${ }^{8}$ The PACS is a contract binding two individuals in a similar, but more flexible way than marriage. It is also available to same-sex couples.

[^5]:    ${ }^{9}$ According to INSEE ERFS data

[^6]:    ${ }^{10}$ What we call children is in reality a broader category: it can include young unmarried adults (below 21, or 25 for students), as well as dependent people, like disabled people or old parents. We call this category "children" for simplicity, because it is the most frequent case.

[^7]:    ${ }^{11}$ This is no official term, and is not used by the tax administration. We call "marriage subsidy" the tax reduction that results from marriage in the current design of French income tax. Similarly, there is no clear information provided to taxpayers as regards the tax gain provided by their children; our "no children" computation is purely contrafactual, and is normally not given to the taxpayer.
    ${ }^{12}$ net of working expenses

[^8]:    ${ }^{13} 2007$ income tax, on 2006 income

[^9]:    ${ }^{14}$ According to official statistics of the French government: http://www2.impots.gouv.fr/ documentation/statistiques/annuaire2007

[^10]:    ${ }^{15}$ Different schemes are available (monthly, quarterly, ...), but the one-year delay remains the rule, and it allows to minimize the number of transactions by deducting PPE benefits from taxpayer's due income tax.

[^11]:    ${ }^{16}$ The concept of fiscal parts, a value increasing in the number of children, which is at the center of the French income tax system, is described in section 4.2.2.
    ${ }^{17}$ In order to compute $\alpha$, the tax administration computes $\alpha=\frac{\text { hours worked }}{1800}$, and an equivalent formula with the number of days worked.

[^12]:    ${ }^{18}$ Implicit marginal rate of taxation is the loss of PPE benefits triggered by a small variation in labor income.
    ${ }^{19}$ Increases are computed for each PPE beneficiary of the household, but only the most beneficial one is applied, and given to the household as a whole.

[^13]:    ${ }^{20}$ www.caf.fr
    ${ }^{21}$ In order to provide up-to-date information, we give 2009 schedules. The parameters have been converted back to 2008 value in the simulator. The government had increased them by $3 \%$ between 2008 and 2009.
    ${ }^{22}$ These are not synonyms; see the paragraph about increases( majorations).

[^14]:    ${ }^{23}$ This change implies that children of age 11 in 2009 bring a $36,86 €$ increase if they were born during the first semester, and nothing if they were born in the second semester. Since we do not observe children's day and month of birth in the data, we randomly attribute this amount to half of the families concerned.
    ${ }^{24}$ Otherwise stated, the original amount of $161,29 €$ is decreased by $8,6 €$ if the family earns $100 €$ more than the upper limit, and so on.
    ${ }^{25}$ These other specific direct transfers have not yet been implemented in the simulator.

[^15]:    ${ }^{26}$ the marginal tax rate of RSA benefits, which we integrate in our new schedule, being higher than the marginal tax rate of income tax, except for very large levels of income

[^16]:    ${ }^{27}$ In the case of couples presented in household-specific tables, an income-weighting is also done between spouses.
